Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

Developed by the HHS Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children—A Working Group of the Office of AIDS Research Advisory Council (OARAC)

How to Cite the Pediatric Guidelines:

Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. Available at http://aidsinfo.nih.gov/contentfiles/ivguidelines/pediatricguidelines.pdf. Accessed (insert date) [include page numbers, table number, etc. if applicable]

Use of antiretrovirals in pediatric patients is evolving rapidly. These guidelines are updated regularly to provide current information. The most recent information is available at http://aidsinfo.nih.gov.
What’s New in the Pediatric Guidelines  (Last updated March 5, 2015; last reviewed March 5, 2015)

Key changes made by the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel) to update the February 12, 2014, Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection are summarized below. Throughout the document, text and references have been updated to include new publications where relevant. Minor changes and edits have been made to enhance clarity and facilitate use of the Guidelines. The Panel has added a new section to address specific issues in antiretroviral therapy (ART) for neonates. All changes are highlighted.

Diagnosis of HIV Infection

• Because children with perinatal HIV exposure aged 18 to 24 months may have residual maternal HIV antibodies, the Panel recommends that definitive exclusion or confirmation of HIV infection in children in this age group who are HIV antibody-positive should be based on a nucleic acid test (NAT) (AII).
• The AMPLICOR® HIV-1 DNA test, widely used for diagnosis of infants born to HIV-1-infected mothers since 1992, is no longer commercially available in the United States. The Panel cautions that the sensitivity and specificity of non-commercial HIV-1 DNA tests may differ from the sensitivity and specificity of the Food and Drug Administration (FDA)-approved commercial test.

Clinical and Laboratory Monitoring of Pediatric HIV Infection

• Because current pediatric HIV classification and thresholds for treatment initiation are based on absolute CD4 cell count, the Panel now recommends that absolute CD4 T lymphocyte (CD4) cell count should be used for monitoring immune status in children of all ages, with CD4 percentage as an alternative (AII).
• The Panel has added hepatitis B virus (HBV) screening to the schedule for clinical and laboratory monitoring in Table 3 when considering starting or changing to antiretroviral (ARV) drugs with activity against HBV, specifically lamivudine-, emtricitabine-, and tenofovir-containing regimens.
• The Panel has added Table 4 to provide information about primary, FDA-approved assays to monitor viral load.

When to Initiate Therapy in Antiretroviral-Naive Children

• The Panel has updated recommendations for when to initiate therapy in ARV-naive HIV-infected children to incorporate the updated Centers for Disease Control and Prevention (CDC) Surveillance Case Definition for HIV Infection, which aligns children with adult and adolescent patients. It includes age-specific CD4 values, indicating a preference for the use of CD4 count over CD4 percentage in all ages (see Revised Surveillance Case Definition for HIV Infection at http://www.cdc.gov/mmwr/pdf/rr/rr6303.pdf). Information about HIV infection stage based on age-specific CD4 cell count or percentage is provided in Table 6, and Table 7 lists HIV-related symptoms.
• The Panel has now stratified the urgency for initiation of combination antiretroviral therapy (cART), recommending urgent initiation in all children younger than 12 months and in those aged 12 months and older with CDC Stage 3-defining opportunistic illnesses or Stage 3 CD4 counts. The text provides guidance that in situations requiring urgent initiation of treatment, the clinical team should expedite a discussion on adherence and provide increased, intensive follow-up in the first few weeks to support the children and families.
What Drugs to Start: Initial Combination Therapy for Antiretroviral Treatment-Naive Children

- The Panel has added integrase strand transfer inhibitor-based regimens as agents to be used in combination with two nucleoside analogue reverse transcriptase inhibitors (NRTIs). Raltegravir can be used in children age 2 years and older and dolutegravir in children aged 12 years and older. Raltegravir is also licensed for infants as young as 4 weeks but the Panel would consider usage only in special circumstances.
- The protease inhibitor (PI) atazanavir boosted with ritonavir is now considered an alternative PI in children aged 3 months through 5 years and remains a preferred drug for children 6 years and older.
- The two-NRTI combination of zidovudine and lamivudine or emtricitabine is now considered an alternative combination for adolescents older than 13 years.

Specific Issues in Antiretroviral Therapy for Neonates

- The Panel has added a new section about ART for neonates to address specific issues raised by the ability to diagnose HIV infection within a few days of birth in conjunction with growing discussion and reports of early intensive ART of HIV-infected infants and infants at high risk of HIV infection.
- Available information about dosing and safety of individual ARV drugs in term and pre-term infants is summarized and discussed in the context of the benefits and risks of early intensive treatment.
- The Panel cautions that existing pharmacokinetic (PK) and safety data are insufficient for the recommendation of a complete combination antiretroviral therapy (cART) regimen to treat preterm infants and term infants younger than 15 days (until 42 weeks postmenstrual age).
- The Panel recommends that neonatal care providers who are considering a three-drug ARV treatment regimen of term infants younger than 2 weeks or premature infants contact a pediatric HIV expert for guidance and individual case assessment of the risk/benefit ratio of treatment and for the latest information on neonatal drug doses. The National Perinatal HIV Hotline (1-888-448-8765) provides free clinical consultation on perinatal HIV care.

Management of Medication Toxicity

- Toxicity table sections have been reviewed and updated throughout. Notable changes include newer data on the occurrence and management of central nervous system (CNS) adverse effects of efavirenz and the effects on creatinine determination of newer ARV drugs dolutegravir, cobicistat, and rilpivirine.
- Central Nervous System Toxicity: The toxicity table has been updated to reflect recent reports indicating that a greater proportion of patients than previously recognized experience persistent CNS symptoms due to efavirenz and new information about suicidality associated with this drug. Major depression or suicidal thoughts are now specified as psychiatric illnesses warranting cautious use of efavirenz. Explicit recommendation is made to discontinue efavirenz for severe and/or persistent symptoms when a suitable alternative exists.
- Nephrotic Effects: The toxicity table has been updated to include a section about elevation in serum creatinine with drugs that cause an asymptomatic decrease in renal tubular secretion of creatinine, leading to an increase in measured serum creatinine without a true change in glomerular filtration rate: dolutegravir, cobicistat, rilpivirine.

Modifying Antiretroviral Regimens in Children with Sustained Virologic Suppression on Antiretroviral Therapy

- The Panel has added a new bulleted recommendation to emphasize the need to consider past episodes of ARV treatment failure, tolerability, and all prior drug resistance testing results to avoid choosing new ARV
drugs for which archived drug resistance would limit activity.

- Updated ARV drug information has been incorporated in the text and in Table 14 which provides examples of changes in ARV regimen components that are made for reasons of simplification, convenience, and safety profile in children who have sustained virologic suppression on their current regimen.

Role of Therapeutic Drug Monitoring in the Management of Pediatric HIV Infection

- The Panel has added language about consideration of dose adjustment for efavirenz with a known CYP2B6 poor metabolizer genotype in children older than 3 years.

Pediatric Antiretroviral Drug Information

- Updates with new pediatric data are provided when relevant to specific drugs. The Panel has added and revised references to websites in each drug section that provide information about drug interactions http://www.hiv-druginteractions.org/ and HIV resistance mutations http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf and http://hivdb.stanford.edu/DR/. With FDA approval of cobicistat tablets, a new heading has been added for drugs classified as Pharmacokinetic Enhancers.

Nucleoside Analogue Reverse Transcriptase Inhibitors

- **Zidovudine:** The Panel has updated the dosing table to include the dose for continuation of zidovudine after 4 or more weeks based on gestational age.

Non-Nucleoside Analogue Reverse Transcriptase Inhibitors

- **Nevirapine:** The Panel has provided information about the investigational treatment dose of nevirapine for infants younger than 1 month with a link to the new section, Dosing: Special Considerations: Neonates ≤14 Days and Premature Infants.

- **Rilpivirine:** The panel has updated dosing for adolescents and adults to include switching to rilpivirine in appropriate virologically-suppressed patients.

Protease Inhibitors

- **Atazanavir:** In June 2014, the FDA approved the powder formulation of atazanavir for infants and children 3 months and older who weigh at least 10 kg but less than 25 kg. The Panel provides information about dosing and administration of atazanavir powder and discusses issues related to transitioning from atazanavir powder to capsules. Because there is no FDA approved atazanavir powder dose for the child who reaches a weight of 25 kg and cannot swallow pills, the Panel has provided information about an experimental dose currently under study for children who weigh 25 to <35kg. Information is also provided about the use of cobicistat tablets for boosting atazanavir in adolescents 18 years and older and adults. Information has also been added about administration and dosing of atazanavir with cobicistat in adolescents and adults.

- **Darunavir:** Information has been added about administration and dosing of darunavir with cobicistat in adolescents 18 years and older and adults.

Integrase Strand Transfer Inhibitors

- **Dolutegravir:** The Panel has provided information about the investigational dose being used in a clinical trial for treatment-experienced children younger than 12 years.

- **Elvitegravir:** A tablet formulation of elvitegravir was FDA approved in September 2014 for adults; it is not approved for children younger than 18 years. The Panel has provided dosing recommendations for the use of elvitegravir in combination with other ARV drugs.
**Pharmacokinetic Enhancers**

- **Cobicistat:** A new section has been added because cobicistat is now available as a tablet and in combination with atazanavir (Evotaz) or darunavir (Prezco) as well as the previously available Stribild (emtricitabine-tenofovir disoproxil fumarate-elvitegravir-cobicistat). Cobicistat is not interchangeable with ritonavir. See dosing information for specific PI and elvitegravir that require cobicistat for boosting.

- **Ritonavir:** Information about ritonavir has been moved because it is used as a PK enhancer of other PI in children and adults and is no longer recommended as an antiviral agent. In adults, ritonavir is recommended as a PK enhancer for use with the integrase inhibitor elvitegravir, when used in combination with another PI.
Table of Contents

What’s New in the Guidelines ........................................................................................................... i
Guidelines Panel Members .................................................................................................................. ix
Financial Disclosure ........................................................................................................................... xi

Introduction ......................................................................................................................................... A-1

Introduction (Last updated March 5, 2015; last reviewed March 5, 2015)

These updated guidelines address the use of combination antiretroviral therapy (cART) for HIV-infected infants, children, and adolescents (through puberty). Guidance on management of adverse events associated with use of antiretroviral (ARV) drugs in children and a detailed review of information about safety, efficacy, and pharmacokinetics (PK) of ARV agents in children is also included. The Department of Health and Human Services (HHS) Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel), a working group of the Office of AIDS Research Advisory Council (OARAC), reviews new data on an ongoing basis and provides regular updates to the guidelines. The guidelines are available on the AIDSinfo website at https://aidsinfo.nih.gov.

The AIDSinfo website also includes separate guidelines for the prevention and treatment of opportunistic infections in HIV-exposed and -infected children, for the use of ARV agents in HIV-infected (post–pubertal) adolescents and adults, for the use of ARV drugs in pregnant HIV-infected women, and for the prevention and treatment of opportunistic infections in HIV-infected adults. These guidelines are developed for the United States and may not be applicable in other countries. The World Health Organization (WHO) provides guidelines for resource-limited settings at http://www.who.int/hiv/pub/arv/en.

Since the guidelines were first developed in 1993 (with the support of the François-Xavier Bagnoud Center, Rutgers, The State University of New Jersey), advances in medical management have dramatically reduced morbidity and mortality in HIV-infected children in the United States. Mortality in children with perinatal HIV infection has decreased by more than 80% to 90% since the introduction of protease inhibitor-containing combinations and opportunistic and other related infections in children have significantly declined in the era of cART. ARV drug resistance testing has enhanced the ability to choose effective initial and subsequent regimens. Treatment strategies continue to focus on timely initiation of cART regimens capable of maximally suppressing viral replication in order to prevent disease progression, preserve or restore immunologic function, and reduce the development of drug resistance. At the same time, availability of new drugs and drug formulations has led to more potent regimens with lower toxicity, lower pill burdens, and less frequent medication administration, all factors that can improve adherence and outcomes. The use of ARV drugs in HIV-infected pregnant women has resulted in a dramatic decrease (to less than 2%) in the rate of HIV transmission to infants in the United States. In addition to decreasing numbers of infants with HIV infection, children in the United States who are HIV-infected are less likely to develop AIDS because of routine and early institution of effective cART. Finally, as a group, children living with HIV infection are growing older, bringing new challenges related to adherence, drug resistance, reproductive health planning, transition to adult medical care, and the potential for long-term complications from HIV and its treatments.

The pathogenesis of HIV infection and the virologic and immunologic principles underlying the use of cART are generally similar for all HIV-infected individuals, but unique considerations exist for HIV-infected infants, children, and adolescents, including:

- Acquisition of infection through perinatal exposure for most infected children;
- In utero, intrapartum, and/or postpartum neonatal exposure to ARV drugs in most perinatally infected children;
- Requirement for use of HIV virologic tests to diagnose perinatal HIV infection in infants younger than 18 months;
- Age-specific interpretation of CD4 T lymphocyte (CD4) cell counts;
- Higher viral loads in perinatally-infected infants than in HIV-infected adolescents and adults;
- Changes in PK parameters with age caused by the continuing development and maturation of organ systems involved in drug absorption, distribution, metabolism, and clearance;
- Differences in the clinical manifestations and treatment of HIV infection secondary to onset of infection...
in growing, immunologically immature individuals; and

- Special considerations associated with adherence to ARV treatment in infants, children, and adolescents.

The recommendations in these guidelines are based on the current state of knowledge regarding the use of ARV drugs in children. Evidence is drawn primarily from published data regarding the treatment of HIV infection in infants, children, adolescents, and adults; however, when no such data were available, unpublished data and the clinical expertise of the Panel members were also considered. The Panel intends for these guidelines to be flexible and not to replace the clinical judgment of experienced health care providers.

### Guidelines Development Process

An outline of the composition of the Panel and the guidelines process can be found in Table 1.

**Table 1. Outline of the Guidelines Development Process**  (page 1 of 2)

<tbody>
<tr>
<td><strong>Goal of the Guidelines</strong></td>
<td>Provide guidance to HIV care practitioners on the optimal use of ARV agents in HIV-infected infants, children, and adolescents (through puberty) in the United States.</td>
</tr>
<tr>
<td><strong>Panel Members</strong></td>
<td>The Panel is composed of approximately 32 voting members who have expertise in management of HIV infection in infants, children, and adolescents. Members include representatives from the Committee on Pediatric AIDS of the American Academy of Pediatrics and community representatives with knowledge of pediatric HIV infection. The Panel also includes at least one representative from each of the following HHS agencies: Centers for Disease Control and Prevention (CDC), Food and Drug Administration (FDA), Health Resources and Services Administration (HRSA), and the National Institutes of Health (NIH). A representative from the Canadian Pediatric AIDS Research Group participates as a nonvoting, <em>ex officio</em> member of the Panel. The U.S. government representatives are appointed by their respective agencies; nongovernmental members are selected after an open announcement to call for nominations. Each member serves on the Panel for a 3-year term with an option for reappointment. A list of current members can be found in the <a href="http://aidsinfo.nih.gov">Panel Roster</a>.</td>
</tr>
<tr>
<td><strong>Financial Disclosure</strong></td>
<td>All members of the Panel submit a financial disclosure statement in writing annually, reporting any association with manufacturers of ARV drugs or diagnostics used for management of HIV infections. A list of the latest disclosures is available on the <a href="http://aidsinfo.nih.gov">AIDSinfo website</a>.</td>
</tr>
<tr>
<td><strong>Users of the Guidelines</strong></td>
<td>Providers of care to HIV-infected infants, children, and adolescents</td>
</tr>
<tr>
<td><strong>Developer</strong></td>
<td>Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children—a working group of QARAC</td>
</tr>
<tr>
<td><strong>Funding Source</strong></td>
<td>Office of AIDS Research, NIH and Health Resources and Services Administration</td>
</tr>
<tr>
<td><strong>Evidence Collection</strong></td>
<td>A standardized review of recent relevant literature related to each section of the guidelines is performed by a representative of the François-Xavier Bagnoud Center and provided to individual Panel section working groups. The recommendations are generally based on studies published in peer-reviewed journals. On some occasions, particularly when new information may affect patient safety, unpublished data presented at major conferences or prepared by the FDA and/or manufacturers as warnings to the public may be used as evidence to revise the guidelines.</td>
</tr>
<tr>
<td><strong>Recommendation Grading</strong></td>
<td>Described in <a href="#">Table 2</a>.</td>
</tr>
<tr>
<td><strong>Method of Synthesizing Data</strong></td>
<td>Each section of the guidelines is assigned to a small group of Panel members with expertise in the area of interest. The members synthesize the available data and propose recommendations to the Panel. The Panel discusses and votes on all proposals during monthly teleconferences. Proposals endorsed by a consensus of members are included in the guidelines as official Panel recommendations.</td>
</tr>
</tbody>
</table>
### Basis for Recommendations

Recommendations in these guidelines are based upon scientific evidence and expert opinion. Each recommendation includes a letter (A, B, or C) that represents the strength of the recommendation and a Roman numeral (I, II, or III) that represents the quality of the evidence that supports the recommendation.

Because licensure of drugs in children often is based on efficacy data from adult trials in addition to safety and PK data from studies in children, recommendations for ARV drugs may need to rely, in part, on data from clinical trials or studies in adults. Pediatric drug approval may be based on evidence from adequate and well-controlled investigations in adults if:

1. The course of the disease and the effects of the drug in the pediatric and adult populations are expected to be similar enough to permit extrapolation of adult efficacy data to pediatric patients;
2. Supplemental data exist on PKs of the drug in children indicating that systemic exposure in adults and children are similar; and
3. Studies are provided that support the safety of the drug in pediatric patients.11

Studies relating activity of the drug-to-drug levels (pharmacodynamic data) in children also should be available if there is a concern that concentration-response relationships might be different in children. In many cases, evidence related to use of ARV drugs is substantially greater from adult studies (especially randomized clinical trials) than from pediatric studies. Therefore, for pediatric recommendations, the following rationale has been used when the quality of evidence from pediatric studies is limited:

### Quality of Evidence Rating I—Randomized Clinical Trial Data

- Quality of Evidence Rating I will be used if there are data from large randomized trials in children with clinical and/or validated laboratory endpoints.
- Quality of Evidence Rating I* will be used if there are high-quality randomized clinical trial data in adults with clinical and/or validated laboratory endpoints and pediatric data from well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes that are consistent with the adult studies. A rating of I* may be used for quality of evidence if, for example, a randomized

</tr>
</thead>
<tbody>
<tr>
<td>Other Guidelines</td>
<td>These guidelines focus on HIV-infected infants, children, and adolescents through puberty. For more detailed discussion of issues of treatment of postpubertal adolescents, the Panel defers to the designated expertise offered by the Panel on Antiretroviral Guidelines for Adults and Adolescents. Separate guidelines outline the use of cART in HIV-infected pregnant women and interventions for prevention of perinatal transmission, cART for nonpregnant HIV-infected adults and postpubertal adolescents, and ARV prophylaxis for those who experience occupational or nonoccupational exposure to HIV. These guidelines are also available on the AIDSinfo website (<a href="http://www.aidsinfo.nih.gov">http://www.aidsinfo.nih.gov</a>).</td>
</tr>
<tr>
<td>Update Plan</td>
<td>The full Panel meets monthly by teleconference to review data that may warrant modification of the guidelines. Smaller working groups of Panel members hold additional teleconferences to review individual drug sections or other specific topics (e.g., What to Start). Updates may be prompted by new drug approvals (or new indications, formulations, or frequency of dosing), new significant safety or efficacy data, or other information that may have a significant impact on the clinical care of patients. In the event of significant new data that may affect patient safety, the Panel may issue a warning announcement and post accompanying recommendations on the AIDSinfo website until the guidelines can be updated with appropriate changes. All sections of the guidelines will be reviewed, with updates as appropriate, at least once yearly.</td>
</tr>
<tr>
<td>Public Comments</td>
<td>A 2-week public comment period follows release of the updated guidelines on the AIDSinfo website. The Panel reviews comments received to determine whether additional revisions to the guidelines are indicated. The public may also submit comments to the Panel at any time at <a href="mailto:contactus@aidsinfo.nih.gov">contactus@aidsinfo.nih.gov</a>.</td>
</tr>
</tbody>
</table>
Phase III clinical trial in adults demonstrates a drug is effective in ARV-naive patients and data from a nonrandomized pediatric trial demonstrate adequate and consistent safety and PK data in the pediatric population.

Quality of Evidence Rating II—Nonrandomized Clinical Trials or Observational Cohort Data

- Quality of Evidence Rating II will be used if there are data from well-designed nonrandomized trials or observational cohorts in children.
- Quality of Evidence Rating II* will be used if there are well-designed nonrandomized trials or observational cohort studies in adults with supporting and consistent information from smaller nonrandomized trials or cohort studies with clinical outcome data in children. A rating of II* may be used for quality of evidence if, for example, a large observational study in adults demonstrates clinical benefit to initiating treatment at a certain CD4 cell count and data from smaller observational studies in children indicate that a similar CD4 cell count is associated with clinical benefit.

Quality of Evidence Rating III—Expert opinion

- The criteria do not differ for adults and children.

In an effort to increase the amount and improve the quality of evidence available for guiding management of HIV infection in children, the discussion of available trials with children and their caregivers is encouraged. Information about clinical trials for HIV-infected adults and children can be obtained from the AIDSinfo website (http://aidsinfo.nih.gov/ClinicalTrials/) or by telephone at 1-800-448-0440.

Identification of Perinatal HIV Exposure  (Last updated March 5, 2015; last reviewed March 5, 2015)

Panel’s Recommendations

- HIV testing early in pregnancy is recommended as standard of care for all pregnant women in the United States (AII).
- Repeat HIV testing in the third trimester, before 36 weeks’ gestation, should be considered for all HIV-seronegative pregnant women and is recommended for pregnant women who are at high risk of HIV infection (AIII).
- Rapid or expedited HIV testing at the time of labor or delivery should be performed on women with undocumented HIV status; if results are positive, intrapartum and infant postnatal antiretroviral prophylaxis should be initiated immediately, pending results of the confirmatory HIV antibody test (AII).
- Women who have not been tested for HIV before or during labor should undergo rapid or expedited HIV antibody testing during the immediate postpartum period or their newborns should undergo rapid HIV antibody testing. If results in mother or infant are positive, infant antiretroviral prophylaxis should be initiated immediately and the mothers should not breastfeed unless confirmatory HIV antibody testing is negative (AII). In infants with initial positive HIV viral tests (RNA, DNA), prophylaxis should be stopped and antiretroviral treatment initiated.
- For HIV-seronegative women in whom acute HIV infection is suspected during pregnancy, intrapartum, or while breastfeeding, a virologic test (e.g., plasma HIV RNA assay, antigen/antibody combination immunoassay) should be performed because serologic testing may be negative at this early stage of infection (AII).
- Results of maternal HIV testing should be documented in the newborn’s medical record and communicated to the newborn’s primary care provider (AIII).
- Infant HIV antibody testing to determine HIV exposure should be considered for infants in foster care and adoptees for whom maternal HIV infection status is unknown (AII).

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

† Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

HIV infection should be identified prior to pregnancy or as early in pregnancy as possible. This provides the best opportunity to prevent infant HIV infection and to identify and start therapy as soon as possible in infants who become infected. Universal HIV counseling and voluntary HIV testing are recommended as the standard of care for all pregnant women in the United States by The Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel), the U.S. Public Health Service, the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the U.S. Preventive Services Task Force. All HIV testing should be performed in a manner consistent with state and local laws (http://nccc.ucsf.edu/clinical-resources/hiv-aids-resources/state-hiv-testing-laws/). The Centers for Disease Control and Prevention (CDC) recommends the “opt-out” approach, which involves notifying pregnant women that HIV testing will be performed as part of routine care unless they choose not to be tested for HIV. The “opt-in” approach involves obtaining specific consent before testing and has been associated with lower testing rates. The mandatory newborn HIV testing approach, adopted by several states, involves testing of newborns for perinatal HIV exposure with or without maternal consent, if prenatal or intrapartum maternal testing is not performed.

Early identification of HIV-infected women is crucial for their health and for the care of their children, whether the children are infected or not. Knowledge of antenatal maternal HIV infection enables:
• HIV-infected women to receive appropriate combination antiretroviral therapy (cART) and prophylaxis against opportunistic infections for their own health, which may also decrease risk of transmission to their partners.²,⁹,¹⁰

• Provision of cART to the mother during pregnancy and labor, and antiretroviral (ARV) prophylaxis to the newborn to reduce the risk of perinatal transmission of HIV;⁴

• Counseling of HIV-infected women about the indications for (and potential benefits of) scheduled elective cesarean delivery to reduce perinatal transmission of HIV;⁴,¹¹-¹³

• Counseling of HIV-infected women about the risks of HIV transmission through breast milk (breastfeeding is not recommended for HIV-infected women living in the United States and other countries where safe alternatives to breast milk are available);¹⁴

• Initiation of prophylaxis against Pneumocystis jirovecii pneumonia beginning at age 4 to 6 weeks in all HIV-infected infants and in those HIV-exposed infants whose HIV infection status remains indeterminate;¹⁵ and

• Early diagnostic evaluation of HIV-exposed infants, as well as testing of partners and other children, to permit prompt initiation of cART in infected individuals.¹,¹⁶

Repeat HIV Testing in the Third Trimester

Repeat HIV testing should be considered for all HIV-seronegative pregnant women. A second HIV test during the third trimester, before 36 weeks’ gestation, is recommended⁴,¹⁷ for women who:

• Are receiving health care in a jurisdiction that has a high incidence of HIV or AIDS in women between ages 15 and 45, or are receiving health care in facilities in which prenatal screening identifies at least 1 HIV-infected pregnant woman per 1,000 women screened (a list of areas where such screening is recommended is found in the 2006 CDC recommendations);

• Are known to be at high risk of acquiring HIV (e.g., those who are injection drug users or partners of injection drug users, exchange sex for money or drugs, are sex partners of HIV-infected individuals, have had a new or more than one sex partner during current pregnancy, or have been diagnosed with a new sexually transmitted disease during pregnancy); or

• Have signs or symptoms of acute HIV infection.²,³,¹⁸,¹⁹

Women who decline testing earlier in pregnancy should be offered testing again during the third trimester. If acute HIV infection is a possibility, virologic testing with a plasma HIV RNA assay or, if unavailable, an antigen/antibody combination immunoassay, should be performed because serologic testing may be negative at this early stage of infection.²⁰

Rapid HIV Testing During Labor in Women with Unknown HIV Status

Use of rapid test kits or an expedited immunoassay to detect HIV infection is recommended to screen women in labor whose HIV status is undocumented and to identify HIV exposure in their infants.¹,³,⁵,¹⁶ Any hospital offering intrapartum care should have rapid or expedited HIV testing available and should have policies and procedures in place to ensure that staff are prepared to provide patient education about rapid or expedited HIV testing, that results are available ideally within 1 hour, that appropriate ARV medications are available whenever needed, and that follow-up procedures are in place for women found to be HIV-infected and their infants. Rapid tests have been found to be feasible, accurate, timely, and useful both in ensuring prompt initiation of intrapartum and neonatal ARV prophylaxis and in reducing perinatal transmission of HIV.²¹ Results of rapid tests can be obtained within minutes to a few hours with accuracy comparable to standard enzyme-linked immunosorbent assays (EIA).²²,²³ A single negative rapid test does not need confirmation unless acute HIV infection is a possibility, in which case, a virologic test is necessary.²⁰ A positive rapid HIV test result must be followed by a supplemental test to confirm the presence of HIV infection.²³ However,
immediate initiation of ARV prophylaxis for prevention of perinatal transmission of HIV is strongly recommended pending confirmation of an initial positive rapid HIV test.\textsuperscript{1,4,6,16}

**HIV Counseling and Testing During the Postnatal Period**

Women who have not been tested for HIV before or during labor should be offered rapid or expedited testing during the immediate postpartum period or their newborns should undergo rapid or expedited HIV testing with maternal consent (unless state law allows testing without consent).\textsuperscript{1,3,4,16} Use of rapid or expedited HIV assays or expedited EIA for prompt identification of HIV-exposed infants is essential because neonatal ARV prophylaxis should be initiated as soon as possible after birth—ideally no more than 6 to 12 hours after birth—to be effective for the prevention of perinatal transmission. When an initial HIV test is positive in mother or infant, initiation of infant ARV prophylaxis and counseling against initiation of breastfeeding is strongly recommended pending results of confirmatory HIV tests.\textsuperscript{4} If confirmatory tests are negative and acute HIV infection is excluded, infant ARV prophylaxis can be discontinued. In the absence of ongoing maternal HIV exposure, breastfeeding can be initiated. Mechanisms should be developed to facilitate HIV screening for infants who have been abandoned and are in the custody of the state.

**Infant HIV Testing when Maternal HIV Test Results Are Unavailable**

When maternal HIV test results are unavailable (e.g., for infants who are in foster care) or their accuracy cannot be evaluated (e.g., for infants adopted from a country where results are not reported in English), HIV antibody testing is indicated to identify HIV exposure in those infants.\textsuperscript{1} If antibody testing is positive, further testing is needed to diagnose HIV infection, or in the case of infants older than 18 months, to confirm HIV infection (see Diagnosis of HIV Infection in Infants).

**Acute Maternal HIV Infection During Pregnancy or Breastfeeding**

The risk of perinatal transmission of HIV is increased in infants born to women who have acute HIV infection during pregnancy or lactation.\textsuperscript{17,24-28} When acute retroviral syndrome is a possibility in pregnancy or during breastfeeding, maternal testing should include a combination antigen/antibody immunoassay or plasma HIV RNA test, because HIV antibody testing may be negative in early maternal infection. Women with possible acute HIV infection who are breastfeeding should stop breastfeeding immediately until HIV infection is confirmed or excluded.\textsuperscript{14} Pumping and temporarily discarding breast milk can be recommended and (if HIV infection is excluded), in the absence of ongoing maternal exposure to HIV, breastfeeding can resume. Care of pregnant or breastfeeding women identified with acute or early HIV infection, and their infants, should follow the recommendations in the Perinatal Guidelines.\textsuperscript{4}

**Surveillance Reporting of HIV-Exposed Infants to Local and State Health Departments**

Clinicians should be aware of public health surveillance systems and exposed-infant reporting regulations that may exist in their jurisdictions; this is in addition to mandatory reporting of HIV-infected persons, including infants. Reporting cases allows for appropriate public health functions to be accomplished.

**References**

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

Diagnosis of HIV Infection in Infants and Children (Last updated March 5, 2015; last reviewed March 5, 2015)

Diagnosis of HIV Infection in Infants and Children

Virologic assays that directly detect HIV must be used to diagnose HIV infection in infants younger than 18 months; antibody tests should not be used (AI).

HIV RNA and HIV DNA nucleic acid tests (NATs) are recommended as preferred virologic assays (AI).

Virologic diagnostic testing in infants with known perinatal HIV exposure is recommended at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months (AI).

Virologic diagnostic testing at birth should be considered for infants at high risk of HIV infection (AI).

Virologic diagnostic testing should be considered 2 to 4 weeks after cessation of antiretroviral (ARV) prophylaxis for infants receiving combination ARV infant prophylaxis, if the results of prior virologic testing were negative while the infant was receiving prophylaxis (BII).

A positive virologic test should be confirmed as soon as possible by a repeat virologic test on a second specimen (AI).

Definitive exclusion of HIV infection in non-breastfed infants is based on two or more negative virologic tests, with one obtained at age ≥1 month and one at age ≥4 months, or two negative HIV antibody tests from separate specimens obtained at age ≥6 months (AI).

Some experts confirm the absence of HIV infection at 12 to 18 months of age in infants with prior negative virologic tests by performing an antibody test to document loss of maternal HIV antibodies (BIII).

Children with perinatal HIV exposure aged 18 to 24 months may have residual maternal HIV antibodies; definitive exclusion or confirmation of HIV infection in children in this age group who are HIV antibody-positive should be based on a NAT (see Diagnostic Testing in Children with Perinatal HIV Exposure in Special Situations) (AI).

Diagnosis of HIV infection in children with non-perinatal exposure or children with perinatal exposure aged >24 months relies primarily on the use of HIV antibody tests; when acute HIV infection is suspected, testing with an HIV NAT may be necessary to diagnose HIV infection (AI).

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

† Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

Diagnostic Testing in Infants with Perinatal HIV-1 (HIV) Exposure

HIV infection can be definitively diagnosed through use of virologic assays in most non-breastfed HIV-exposed infants by age 1 month and in virtually all infected infants by age 4 months. Tests for antibodies to HIV, including newer tests, do not establish the presence of HIV infection in infants because of transplacental transfer of maternal antibodies to HIV; therefore, a virologic test should be used.12 Positive virologic tests (i.e., nucleic acid tests [NAT]—a class of tests that includes HIV DNA and RNA polymerase chain reaction [PCR] assays, and related RNA qualitative or quantitative assays) indicate likely HIV infection. The first test result should be confirmed as soon as possible by a repeat virologic test on a second specimen because false-positive results can occur with both RNA and DNA assays.

HIV culture is not used for routine HIV diagnostic testing.3 It is more complex and expensive to perform than DNA PCR or RNA assays, requires 2 to 4 weeks for definitive results, and is generally not available outside of research laboratories. Use of the currently approved HIV p24 antigen assay is not recommended.
for infant diagnosis in the United States because the sensitivity and specificity of the assay in the first months of life are less than that of other HIV virologic tests.

Infants who are found to have positive HIV antibody tests but whose mothers’ HIV status is unknown (see Identification of Perinatal HIV Exposure) should be assumed to be HIV-exposed and undergo the HIV diagnostic testing described here.

**HIV DNA PCR**

HIV DNA PCR is a sensitive technique used to detect specific HIV viral DNA in peripheral blood mononuclear cells. The specificity of the HIV DNA PCR is 99.8% at birth and 100% at ages 1, 3, and 6 months. The sensitivity of the test performed at birth is 55% but increases to more than 90% by 2 to 4 weeks of age and to 100% at ages 3 months and 6 months. Although, the AMPLICOR® HIV-1 DNA test has been widely used for diagnosis of infants born to HIV-1-infected mothers since it was introduced in 1992, it is no longer commercially available in the United States. The sensitivity and specificity of non-commercial HIV-1 DNA tests (using individual laboratory reagents) may differ from the sensitivity and specificity of the Food and Drug Administration (FDA)-approved commercial test.

**HIV RNA Assays**

HIV quantitative RNA assays detect extracellular viral RNA in the plasma. Their specificity (for results ≥5,000 copies/mL) has been shown to be 100% at birth and at 1, 3, and 6 months of age and is comparable to HIV DNA PCR. HIV RNA levels <5,000 copies/mL may not be reproducible and should be repeated before they are interpreted as documenting HIV infection in an infant. The sensitivity of HIV RNA assays has been shown to be 25% to 58% during the first weeks of life, 89% at age 1 month, and 90% to 100% by age 2 to 3 months. HIV RNA assays were found to be as sensitive as HIV DNA PCR for early diagnosis of HIV infection in HIV-exposed infants regardless of receipt of infant zidovudine prophylaxis.

An HIV RNA assay can be used as the supplemental test for infants who have an initial positive HIV DNA PCR test. In addition to providing virologic confirmation of infection status, the expense of repeat HIV DNA PCR testing is spared and an HIV RNA measurement is available to assess baseline viral load. HIV RNA assays may be more sensitive than HIV DNA PCR for detecting HIV non-subtype B (see Issues Related to Diagnosis of Group M Non-Subtype B and Group O HIV-1 Infections).

While HIV DNA PCR remains positive in most individuals receiving antiretroviral (ARV) treatment, HIV RNA assays could potentially be affected by maternal antenatal treatment or infant combination ARV prophylaxis. However, in one study, the sensitivity of HIV RNA assays was not associated with the type of maternal or infant ARV prophylaxis, but HIV RNA levels at 1 month were significantly lower in infants receiving multidrug prophylaxis (n = 9) compared to levels among infected infants receiving single-drug zidovudine prophylaxis (n = 47) (median HIV RNA 2.5 log copies/mL vs. 5.4 log copies/mL, respectively). In contrast, the median HIV RNA levels were high (median HIV RNA 5.6 log copies/mL) by age 3 months in both groups after stopping prophylaxis. Further studies are necessary to evaluate the sensitivity of HIV RNA assays during and after receipt of combination infant ARV prophylaxis.

The HIV qualitative RNA assay (APTIMA HIV-1 RNA Qualitative Assay) is an alternative diagnostic test that can be used for infant testing. It is the only qualitative RNA test that is FDA-approved.

**Issues Related to Diagnosis of Group M Non-Subtype B and Group O HIV-1 Infections**

Although HIV-1 Group M subtype B is the predominant viral subtype found in the United States, non-subtype B viruses predominate in other parts of the world, such as subtype C in regions of Africa and India and subtype CRF01 in much of Southeast Asia. Group O HIV strains are seen in West-Central Africa. Non-subtype B and Group O strains may also be seen in countries with links to these geographical regions. Geographical distribution of HIV groups is available at [http://www.hiv.lanl.gov/components/sequence/HIV/geo/geo.comp](http://www.hiv.lanl.gov/components/sequence/HIV/geo/geo.comp).
HIV DNA PCR tests have decreased sensitivity for detection of non-subtype B HIV, and false-negative HIV DNA PCR test results have been reported in infants infected with non-subtype B HIV. In an evaluation of perinatally infected infants diagnosed in New York State in 2001 through 2002, 16.7% of infants were infected with a non-subtype B strain of HIV, compared with 4.4% of infants diagnosed between 1998 and 1999.

Currently available real-time HIV RNA PCR assays and the qualitative RNA assay have improved sensitivity for detection of non-subtype B HIV infection and the more uncommon Group O strains, compared to other RNA assays that do not detect or properly quantify all non-B subtypes and Group O HIV (see HIV RNA Monitoring in Children: General Considerations in Clinical and Laboratory Monitoring).

When evaluating an infant whose mother’s HIV transmission risk is linked to an area endemic for non-subtype B HIV or Group O strains, such as Africa or Southeast Asia, clinicians should consider conducting initial testing using one of the assays more sensitive for non-subtype B viruses, such as one of the real-time PCR assays or the qualitative RNA assay. In addition, when non-subtype B perinatal exposure is suspected in infants with negative HIV DNA PCR results, repeat testing using one of the newer RNA assays is recommended. The child should undergo close clinical monitoring and HIV serologic testing at age 18 months to definitively rule out HIV infection. Clinicians should consult with an expert in pediatric HIV infection; state or local public health departments or the Centers for Disease Control and Prevention (CDC) may be able to assist in obtaining referrals for diagnostic testing.

Issues Related to Diagnosis of HIV-2 Infections

HIV-2 infection is endemic in Angola; Mozambique; West African countries including Cape Verde, Ivory Coast, Gambia, Guinea-Bissau, Mali, Mauritania, Nigeria, Sierra Leone, Benin, Burkina Faso, Ghana, Guinea, Liberia, Niger, Nigeria, Sao Tome, Senegal, and Togo; and parts of India. It also occurs in countries such as France and Portugal, which have large numbers of immigrants from these regions; HIV-2 is rare in the United States. HIV-2 infection should be suspected in pregnant women who are from—or who have partners from—countries in which the disease is endemic, who are HIV-1 antibody-positive on an initial immunoassay test, and who have repeatedly indeterminate results on HIV-1 Western blot and HIV-1 RNA viral loads at or below the limit of detection. This pattern of HIV testing can also be seen in patients who have a false-positive HIV antibody test. HIV-1 and HIV-2 coinfected patients may also occur but are rare outside areas where HIV-2 is endemic. Although accurate diagnosis of HIV-2 can be problematic, it is clinically important because HIV-2 strains are naturally resistant to several ARV drugs developed to suppress HIV-1.

The majority of commercially available HIV screening antibody tests can detect both HIV-1 and HIV-2 but do not distinguish between the two viruses. More than 60% of individuals with HIV-2 infection are misclassified as having HIV-1 by the HIV-1 Western blot. The only FDA-approved antibody test that distinguishes between HIV-1 and HIV-2 is the Bio-Rad Laboratories Multispot HIV-1/HIV-2 rapid test which, in the United States, is being used increasingly as a supplemental test instead of the Western blot. All HIV-2 cases should be reported to the HIV surveillance program of the state or local health department, which can arrange for additional confirmatory testing for HIV-2 by their public health laboratory or the CDC. Confirmatory testing for HIV-2 infection uses an HIV-2 nucleic acid test. HIV-2 RNA is undetectable in at least half of HIV-2-infected persons; thus, tests for HIV-2 proviral DNA may be necessary for definitive diagnosis.

Infants born to HIV-2-infected mothers should be tested for HIV-2 infection with HIV-2-specific virologic assays (HIV-2 DNA PCR testing) at time points similar to those used for HIV-1 testing. HIV-2 virologic assays are not commercially available, but the National Perinatal HIV Hotline (1-888-448-8765) can provide a list of sites that perform this testing. Clinicians should consult with an expert in pediatric HIV infection when caring for infants with suspected or known exposure to HIV-2.

Timing of Diagnostic Testing in Infants with Known Perinatal HIV Exposure

Virologic diagnostic testing of an HIV-exposed infant should be performed at age 14 to 21 days, at age 1 to 2 months, and at age 4 to 6 months. Virologic diagnostic testing should be considered at birth for infants at
high risk of HIV infection and 2 to 4 weeks after discontinuation of prophylaxis for infants receiving combination neonatal ARV regimens (see below).

Confirmation of HIV infection should be based on two positive virologic tests from separate blood samples, regardless of a child’s age. A positive HIV antibody test with supplemental Western blot (or immunofluorescent antibody [IFA] assay) at age ≥18 months generally confirms HIV infection; exceptions include late seroreverters (see Diagnostic Testing in Children with Perinatal HIV Exposure in Special Situations).

HIV infection can be presumptively excluded in non-breastfed infants with two or more negative virologic tests (one at age ≥14 days and one at age ≥4 weeks) or one negative virologic test (i.e., negative NAT [RNA or DNA]) test at age ≥8 weeks, or one negative HIV antibody test at age ≥6 months. Pneumocystis jirovecii pneumonia (PCP) prophylaxis is recommended for infants with indeterminate HIV infection status starting at age 4 to 6 weeks until they are determined to be HIV-uninfected or presumptively uninfected. Thus, initiation of PCP prophylaxis can be avoided or discontinued if an infant has negative virologic tests at ages 2 weeks and ≥4 weeks, or if virologic testing is negative at age ≥8 weeks.

Definitive exclusion of HIV infection in a non-breastfed infant is based on two or more negative virologic tests (i.e., negative NATs [RNA or DNA]), one at age ≥1 month and one at age ≥4 months, or two negative HIV antibody tests from separate specimens obtained at age ≥6 months. For both presumptive and definitive exclusion of HIV infection, a child must have no other laboratory (i.e., no positive virologic test results or low CD4 T lymphocyte [CD4] cell count/percent) or clinical evidence of HIV infection and not be breastfeeding. Many experts confirm the absence of HIV infection in infants with negative virologic tests by performing an antibody test at age 12 to 18 months to document seroreversion to HIV antibody-negative status.

Virologic Testing at Birth (Optional)

Virologic testing at birth should be considered for newborns at high risk of perinatal HIV transmission, such as infants born to HIV-infected mothers who did not receive prenatal care or prenatal ARVs, were diagnosed with acute HIV infection during pregnancy, or who had HIV viral loads >1,000 copies/mL close to the time of delivery. As many as 30% to 40% of HIV-infected infants can be identified by age 48 hours. Prompt diagnosis is critical to allow for discontinuing ARV prophylaxis and instituting early ARV therapy (see When to Initiate Therapy). Blood samples from the umbilical cord should not be used for diagnostic evaluations because of the potential for contamination with maternal blood. Working definitions have been proposed to differentiate acquisition of HIV infection in utero from the intrapartum period. Infants who have a positive virologic test at or before age 48 hours are considered to have early (i.e., intrauterine) infection, whereas infants who have a negative virologic test during the first week of life and subsequent positive tests are considered to have late (i.e., intrapartum) infection.

Virologic Testing at Age 14 to 21 Days

The diagnostic sensitivity of virologic testing increases rapidly by age 2 weeks, and early identification of infection would permit discontinuation of neonatal ARV prophylaxis and initiation of ARV therapy (see Infants Younger than Age 12 Months and Table 5 in When to Initiate Therapy).

Virologic Testing at Age 1 to 2 Months

Infants with negative virologic tests before age 1 month should be retested at age 1 to 2 months. Most HIV-exposed neonates will receive 6 weeks of neonatal ARV prophylaxis. Although the use of antepartum, intrapartum, and neonatal zidovudine single-drug prophylaxis did not delay detection of HIV by culture in infants in Pediatric AIDS Clinical Trials Group protocol 076 or affect the sensitivity and predictive values of many virologic assays, this may not always apply to current combination prenatal and neonatal ARV regimens if the test is obtained while the infant is receiving combination neonatal ARV prophylaxis.

Virologic diagnostic testing for infants receiving combination ARV infant prophylaxis should be considered 2 to 4 weeks after cessation of prophylaxis if prior negative diagnostic testing was performed during the
period of prophylaxis. In such situations, the test recommended at age 1 to 2 months can be delayed until after cessation of ARV prophylaxis.

An infant with two negative virologic tests, one at age ≥14 days and one at age ≥1 month, can be viewed as **presumptively** uninfected and will not need PCP prophylaxis, assuming the child has not had a positive virologic test, CD4 immunosuppression, or clinical evidence of HIV infection.

**Virologic Testing at Age 4 to 6 Months**

HIV-exposed children who have had negative virologic assays at age 14 to 21 days and at age 1 to 2 months, have no clinical evidence of HIV infection, and are not breastfed should be retested at age 4 to 6 months for **definitive** exclusion of HIV infection.

**Antibody Testing at Age 6 Months and Older**

Two or more negative HIV antibody tests performed in non-breastfed infants at age ≥6 months can also be used to **definitively** exclude HIV infection in HIV-exposed children with no clinical or virologic laboratory evidence of HIV infection.

**Antibody Testing at Age 12 to 18 Months to Document Seroreversion**

Some experts confirm the absence of HIV infection in infants with negative virologic tests (when there has not been prior confirmation of two negative antibody tests) by repeat serologic testing between 12 and 18 months of age to confirm that maternal HIV antibodies transferred in utero have disappeared. In a recent study, the median age at seroreversion was 13.9 months. Although the majority of HIV-uninfected infants will serovert by age 15 to 18 months, there are reports of late seroreversion after 18 months (see below). Factors that might influence the time to seroreversion include maternal disease stage and assay sensitivity.

**Diagnostic Testing in Children with Perinatal HIV Exposure in Special Situations**

**Late Seroreversion up to Age 24 Months**

Non-breastfed, perinatally HIV-exposed infants with no other HIV transmission risk and no clinical or virologic laboratory evidence of HIV infection may have residual HIV antibodies up to age 24 months (these infants are called late seroreverters). In one study, 14% seroverted after age 18 months. These children may have positive immunoassay results but indeterminate supplemental antibody tests (using Western blot or IFA). In such cases, repeat antibody testing at a later time would document seroreversion. Due to the possibility of residual HIV antibodies, virologic testing (i.e., with a NAT) will be necessary to **definitively exclude or confirm** HIV infection in children with perinatal HIV exposure at age 18 to 24 months in situations such as lack of prior testing history or clinical suspicion of HIV infection.

**Postnatal HIV Infection in HIV-Exposed Children with Prior Negative Virologic Tests for Whom There Are Additional HIV Transmission Risks**

In contrast to late seroreverters, in rare situations postnatal HIV infections have been reported in HIV-exposed infants who had prior negative HIV virologic tests. This occurs in infants who become infected through an additional risk after completion of testing (see **Diagnostic Testing in Children with Non-Perinatal HIV Exposure or Children with Perinatal Exposure Aged ≥24 Months**). If an HIV antibody test is positive at age 18 to 24 months, repeated virologic testing will distinguish between residual antibodies in uninfected, late-seroverters and true infection.

**Suspicion of HIV-2 or Non-Subtype B HIV-1 Infections with False-Negative Virologic Test Results**

Children with non-subtype B HIV-1 infection and children with HIV-2 infection may have false-negative virologic tests but persistent positive immunossay results and indeterminate HIV-1 Western blot results. The diagnostic approach in these situations is discussed above in the sections in Issues Related to Diagnosis...
of Group M Non-Subtype B and Group O HIV-1 Infections and in Issues Related to Diagnosis of HIV-2 Infections.

**Diagnostic Testing in Children with Non-Perinatal HIV Exposure or Children with Perinatal Exposure Aged >24 Months**

Breastfeeding is a known route of postnatal HIV transmission. Typical scenarios in the United States include women who have not been adequately counseled about infant feeding, women who breastfeed despite being counseled not to do so (this may occur among women from communities where breastfeeding is the norm and/or in women who fear that not breastfeeding would be a stigma or would reveal their HIV status), and women who learn of their HIV diagnosis only after initiating breastfeeding (such as women who were HIV negative during pregnancy but who acquire HIV infection postnatally; breastfeeding during acute HIV infection is associated with an increased risk of perinatal HIV transmission). Donor breast milk from an unscreened HIV-infected donor is an additional potential risk factor. Diagnostic testing to rule out acquisition of HIV through breast milk will only be accurate after breastfeeding has completely ceased. Infants who are breastfed by HIV-infected women should undergo immediate age-appropriate HIV diagnostic testing, and breastfeeding should be discontinued. Follow-up testing should be performed at 4 to 6 weeks, 3 months, and 6 months after breastfeeding cessation if the initial tests are negative. If acute HIV infection or end-stage AIDS is suspected, virologic testing may be necessary to diagnose HIV infection because HIV-1/2 antibody immunoassays, HIV-1 Western blot, or HIV-1 IFA may be negative in these situations.

Additional routes of HIV transmission in children include sexual abuse or receipt of contaminated blood products (which occurs in countries in which parenteral exposure to HIV via contaminated blood products is a possibility). In such cases, maternal HIV status may be negative or unknown.

Acquisition of HIV is possible through accidental needlesticks or behavioral risks, such as sexual activity or injection drug use in older children. Medical procedures performed in settings with inadequate infection control practices may pose a potential risk; although tattooing or body piercing presents a potential risk of HIV transmission, no cases of HIV transmission from these activities have been documented.

Diagnosis of HIV-1 infection in children with non-perinatal exposure or children with perinatal exposure aged >24 months relies primarily on HIV antibody tests. FDA-approved diagnostic tests include:

- Antigen/antibody combination immunoassays (fourth-generation tests) that detect HIV-1/2 antibodies as well as HIV-1 p24 antigen: Recommended for initial testing
- HIV-1/2 immunoassays (third-generation antibody tests): Alternative for initial testing
- HIV-1/HIV-2 antibody differentiation immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies (Multiplex HIV-1/HIV-2 test): Recommended for supplemental testing
- HIV-1 Western blot and HIV-1 indirect IFAs (first-generation tests): Alternative for supplemental testing
- HIV-1 NAT (HIV qualitative RNA assay)

If acute HIV infection or end-stage AIDS is suspected, virologic testing may be necessary to diagnose HIV infection because HIV-1/2 antibody immunoassays, HIV-1 Western blot, or HIV-1 IFA may be negative in these situations.

Clinical and Laboratory Monitoring of Pediatric HIV Infection
(Last updated March 5, 2015; last reviewed March 5, 2015)

Panel’s Recommendations

- Absolute CD4 T lymphocyte (CD4) cell count is recommended for monitoring immune status in children of all ages, with CD4 percentage as an alternative (All).
- CD4 cell count/percentage and plasma HIV RNA (viral load) should be measured at the time of diagnosis of HIV infection and at least every 3 to 4 months thereafter for children not on combination antiretroviral therapy (cART) (All).
- More frequent CD4 cell count and plasma viral load monitoring should be implemented in children with suspected clinical, immunologic, or virologic deterioration or to confirm an abnormal value (All).
- After initiation of cART (or after a change in cART regimen), children should be evaluated for clinical side effects and to support treatment adherence within 1 to 2 weeks, with laboratory testing for toxicity and viral load response recommended at 2 to 4 weeks after treatment initiation (All).
- Children on cART should have therapy adherence, effectiveness (by CD4 cell count/percentage and plasma viral load), and toxicities (by history, physical, and selected laboratory tests) routinely assessed every 3 to 4 months (All*).
- CD4 cell count/percentage can be monitored less frequently (every 6–12 months) in children and youth who are adherent to therapy and have CD4 cell value well above the threshold for opportunistic infection risk, sustained viral suppression, and stable clinical status for more than 2 to 3 years (BII).

Rating of Recommendations: A = Strong; B = Moderate; C = Optional
Rating of Evidence: I = One or more randomized trials in children† with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children† with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children† from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

Laboratory monitoring of HIV-infected children poses unique and challenging issues. In particular, normal ranges and the value of CD4 T lymphocyte (CD4) cell count and plasma HIV-1 RNA concentration (viral load) for prediction of risk of disease progression vary significantly by age. This section will address immunologic, virologic, and general laboratory monitoring as clinical monitoring of HIV-infected children, relevant to both those who are and are not receiving combination antiretroviral therapy (cART).

Immunologic Monitoring in Children: General Considerations

Clinicians interpreting CD4 cell count and percentage in children must consider age as a factor. CD4 cell count and percentage values in healthy infants who are HIV-uninfected are considerably higher than values observed in uninfected adults (and slowly decline to adult values by age 5 years). In children younger than age 5 years, the absolute CD4 cell count tends to vary more with age than does CD4 percentage. Therefore, in HIV-infected children younger than age 5 years, CD4 percentage has historically been preferred for monitoring immune status, whereas absolute CD4 cell count has been the preferred option for children aged ≥5 years. An analysis from the HIV Paediatric Prognostic Markers Collaborative Study (HPPMCS) found that CD4 percentage provided little or no additional prognostic value compared with CD4 cell count regarding short-term disease progression in children aged <5 years as well as in older children. Current pediatric HIV classification and thresholds for treatment initiation are based on absolute CD4 cell count (see When to Initiate).

In HIV-infected children, as in infected adults, the CD4 cell count and percentage decline as HIV infection progresses; patients with lower CD4 cell count/percentage values have a poorer prognosis than patients with
The prognostic value of CD4 cell count and percentage varies with the age of the child. Infants in the first year of life experience higher risks of progression or death than older children for any given CD4 stratum. For example, comparing a 1-year-old child with a CD4 percentage of 25% to a 5-year-old child with the same CD4 percentage, there is an approximately fourfold increase in the risk of AIDS and sixfold increase in the risk of death in the 1-year-old child (see Figures A and B in Appendix C: Supplemental Information). Children aged 5 years or older have a lower risk of progression than younger children, with the increase in risk of AIDS or death corresponding to CD4 cell count more similar to those in young adults (see Figure C and Table B in Appendix C: Supplemental Information). In the HPPMCS, there were no deaths among children aged 5 years or older with CD4 cell count >350 cells/mm³, although in younger children there continued to be a significant risk of death even with CD4 cell count >500 cells/mm³ (see Table B in Appendix C: Supplemental Information).

These risk profiles contribute to the rationale for recommendations on when to initiate therapy in a treatment-naïve HIV-infected child (see When to Initiate). A website using the meta-analysis from the HPPMCS is available to estimate the short-term risk of progression to AIDS or death in the absence of effective cART according to age and the most recent CD4 percentage/absolute CD4 cell count or HIV-1 RNA viral load measurement (http://hppmcs.org).5

Measurement of CD4 cell count and percentage can be associated with considerable intrapatient variation.5 Mild intercurrent illness, the receipt of vaccinations, or exercise can produce a transient decrease in CD4 cell count and percentage; thus, CD4 cell count/percentage are best measured when patients are clinically stable. No decision about therapy should be made in response to a change in CD4 cell count/percentage until the change has been substantiated by at least a second determination, with a minimum of 1 week between measurements.

**HIV RNA Monitoring in Children: General Considerations**

Quantitative HIV-1 RNA assays measure the plasma concentration of HIV RNA as copies/mL, commonly referred to as the plasma viral load. During the period of primary infection in adults and adolescents, in the absence of therapy, plasma viral load initially rises to high peak levels and then declines by as much as 2 to 3 log₁₀ copies to reach a stable lower level (the virologic set point) approximately 6 to 12 months after acute infection.9,10 In infected adults, the stable lower level (or viral set point) correlates with the subsequent risk of disease progression or death in the absence of therapy.11

The pattern of change in plasma viral load in untreated perinatally infected infants differs from that in infected adults and adolescents. High plasma viral load persists in untreated infected children for prolonged periods.12,13 In one prospective study of infants with perinatal infection born prior to antiretroviral (ARV) availability in children, plasma viral loads generally were low at birth (i.e., <10,000 copies/mL), increased to high values by age 2 months (most infants had values >100,000 copies/mL, ranging from undetectable to nearly 10 million copies/mL), and then decreased slowly, with a mean plasma viral load during the first year of life of 185,000 copies/mL.14 After the first year of life, plasma viral load slowly declined over the next few...
Viral load during the first 12 to 24 months after birth showed an average decline of approximately $0.6 \log_{10}$ copies/mL per year, followed by an average decline of $0.3 \log_{10}$ copies/mL per year until age 4 to 5 years. This pattern probably reflects the lower efficiency of an immature but developing immune system in containing viral replication and possibly the rapid expansion of HIV-susceptible cells that occurs with somatic growth.\footnote{18}

High plasma viral load in infants younger than 12 months has been correlated with disease progression and death, but the range of plasma viral loads overlaps considerably in young infants who have rapid disease progression and those who do not.\textsuperscript{12,14} Plasma viral load $>100,000$ copies/mL in older children also has been associated with high risk of disease progression and mortality, particularly if CD4 percentage is $<15\%$ (see Table C in Appendix C: Supplemental Information).\textsuperscript{16,17} The most robust data set available to elucidate the predictive value of plasma viral load for disease progression in children was assembled in the HPPMCS\textsuperscript{4} (see Immunologic Monitoring in Children: General Considerations) in children on no therapy or only zidovudine monotherapy, which showed that the risk of clinical progression to AIDS or death dramatically increases when viral load exceeds 100,000 copies (5.0 $\log_{10}$ copies)/mL; at lower values, only younger children show much variation in risk (see Figures D and E and Table A in Appendix C: Supplemental Information). At any given viral load, infants younger than 1 year were at higher risk of progression than older children, although these differences were less striking than those observed for the CD4 percentage data.

Despite data indicating that high plasma viral load is associated with disease progression, the predictive value of specific HIV RNA concentrations for disease progression and death for an individual child is moderate.\textsuperscript{16} Plasma viral load may be difficult to interpret during the first year of life because values are high and are less predictive of disease progression risk than in older children.\textsuperscript{15} In both HIV-infected children and adults, CD4 cell count or percentage and plasma viral load are independent predictors of disease progression and mortality risk, and use of the two markers together more accurately defines prognosis.\textsuperscript{16,17,19,20}

**Methodological Considerations in Interpretation and Comparability of HIV RNA Assays**

Several different methods can be used for quantitating HIV RNA, each of which has a different level of sensitivity (see Table). Although the results of the assays are correlated, the absolute HIV RNA copy number obtained from a single specimen tested by two different assays can differ by twofold ($0.3 \log_{10}$ copies/mL) or more.\textsuperscript{21,22} If possible, because of the variability among assays in techniques and quantitative HIV RNA measurements, a single HIV RNA assay method should be used consistently to monitor an individual patient.\textsuperscript{23-25}

The predominant HIV-1 subtype in the United States is subtype B—the subtype for which all initial assays were targeted. Current kit configurations for all companies have been designed to detect and quantitate essentially all viral subtypes, with the exception of the uncommon O subtypes.\textsuperscript{26,27} This is important for many regions of the world where non-B subtypes are predominant as well as for the United States, where a small subset of individuals are infected with non-B viral subtypes.\textsuperscript{23,28-32} It is particularly relevant for children who are born outside the United States or to foreign-born parents. Choice of HIV RNA assay, particularly for young children, may be influenced by the amount of blood required for the assay. The NucliSENS assay requires the least blood (100 $\mu$L of plasma), followed by the RT-PCR assays such as the COBAS MapliPrep/TaqMan (1 microliter of plasma) and VERSANT assays (500 microliters of plasma).

Biologic variation in plasma viral load within one person is well documented. In adults, repeated measurement of plasma viral load using the same assay can vary by as much as threefold ($0.5 \log_{10}$ copies/mL) in either direction over the course of a day or on different days.\textsuperscript{19,22} This biologic variation may be greater in infected infants and young children. This inherent biologic variability must be considered when interpreting changes in plasma viral load in children. Thus, on repeated testing, only differences greater than fivefold ($0.7 \log_{10}$ copies/mL) in infants younger than 2 years and greater than threefold ($0.5 \log_{10}$ copies/mL) in children aged 2 years and older should be considered reflective of plasma viral load changes that are biologically and clinically substantial.
Generally, no change in ARV treatment should be made as a result of a change in plasma viral load unless the change is confirmed by a second measurement. Interpretation of plasma viral load for clinical decision making should be done by or in consultation with an expert in pediatric HIV infection because of the complexities of HIV RNA testing and the age-related changes in plasma viral load in children.

Based on accumulated experience with currently available assays, viral suppression is currently defined as a plasma viral load below the detection limit of the assay used (generally <20 to 75 copies/mL). This definition of suppression has been much more thoroughly investigated in HIV-infected adults than in HIV-infected children (see the Adult and Adolescent Antiretroviral Guidelines). Temporary viral load elevations (“blips”) between the level of detection and 500 copies/mL often are detected in adults and children on cART and should not be considered to represent virologic failure as long as the values return to below the level of detection at the time of repeat testing. For definitions and management of virologic treatment failure, see Recognizing and Managing Antiretroviral Treatment Failure in Management of Children Receiving Antiretroviral Therapy. These definitions of viral suppression and virologic failure are recommended for clinical use. Research protocols or surveillance programs may use different definitions.

Clinical and Laboratory Monitoring of Children with HIV Infection

Table 3 provides one proposed general monitoring schedule, which should be adjusted based on the specific cART regimen a child is receiving.

Entry into Care—Baseline Evaluation

At entry into care, HIV-infected children should have a complete age-appropriate medical history, physical examination, and laboratory evaluation (see Table 3). This should include a general medical and social history (e.g., immunizations, nutrition, physical and social environment), evaluation for HIV-specific physical conditions (e.g., growth delay, microcephaly, motor or cognitive neurologic problems), evaluation for HIV-associated laboratory abnormalities (e.g., anemia, leukopenia, thrombocytopenia, elevated glucose, transaminases or creatinine, hypoalbuminemia), and assessment of presence or risk of opportunistic infections (see the Pediatric Opportunistic Infections Guidelines). Laboratory confirmation of HIV infection should be obtained if available documentation is incomplete (see Diagnosis of HIV Infection). CD4 cell count and percentage, as well as plasma HIV RNA measurements (i.e., viral load), should be obtained at entry into care to help guide decisions about timing of cART initiation (see When to Initiate). Genotype resistance testing should be performed, even if cART is not initiated immediately. For patients previously treated with ARV drugs, resistance evaluation requires a complete ARV history (see Antiretroviral Drug-Resistance Testing).

Monitoring of Children Not Receiving Antiretroviral Therapy

Children not receiving cART should be evaluated every 3 to 4 months with measurement of CD4 cell count and percentage and plasma viral load; evaluation of growth and development for signs of HIV-associated change; and laboratory evaluation for HIV-associated conditions including anemia, leukopenia, thrombocytopenia, elevated glucose, transaminases, or creatinine, and hypoalbuminemia. Urinalysis should be obtained every 6 to 12 months to monitor for HIV-associated nephropathy. Opportunistic infection monitoring should follow guidelines appropriate for the child’s exposure history and clinical setting (see the Pediatric Opportunistic Infections Guidelines).

More frequent evaluation may be necessary for children experiencing virologic, immunologic, or clinical deterioration or to confirm an abnormal value.

Initiation of Combination Antiretroviral Therapy—Overview

Readiness for ARV adherence should be assessed prior to starting cART. If abacavir is being considered as part of the regimen, HLA-B*5701 testing should be sent prior to initiation of that ARV, and an alternative
ARV should be used if HLA-B*5701 is positive (see Abacavir in Appendix A: Pediatric Antiretroviral Drug Information). Genotype resistance testing is recommended if not already performed (see Antiretroviral Drug-Resistance Testing).

Children who start cART or who change to a new regimen should be followed to assess effectiveness, tolerability, and adverse effects of the regimen and to evaluate medication adherence. Frequent patient visits and intensive follow-up during the initial months after a new ARV regimen is started are necessary to support and educate the family. The first few weeks of cART can be particularly difficult for children and their caregivers; they must adjust their schedules to allow for consistent and routine administration of medication doses. Children may also experience adverse effects of medications, and both children and their caregivers need assistance to determine whether the effects are temporary and tolerable or are more serious or long-term and require a visit to the clinician. It is critical that providers speak to caregivers and children in a supportive, non-judgmental manner using layman’s terms. This promotes honest reporting and ensures dialogue between providers and both children and their caregiver(s), even when medication adherence is reported to be inconsistent.

**Monitoring of Children Receiving Antiretroviral Therapy**

**Evaluations at Initiation of Combination Antiretroviral Therapy**

At the time of cART initiation, CD4 cell count and percentage and plasma viral load should be measured to establish a baseline to monitor cART benefit. To set the baseline for monitoring cART toxicity (see Management of Medication Toxicity or Intolerance), complete blood count (CBC) and differential, serum chemistries (including electrolytes, creatinine, glucose, hepatic transaminases), urinalysis, and serum lipids (cholesterol, triglycerides) should be measured. CBC allows monitoring of zidovudine-associated anemia, leukopenia, and macrocytosis (see Zidovudine in Appendix A: Pediatric Antiretroviral Drug Information). Electrolytes with anion gap might help identify nucleoside reverse transcriptase inhibitor (NRTI)-associated lactic acidosis. With use of tenofovir disoproxil fumarate, creatinine may increase, phosphate decrease, and proteinuria can occur (see Tenofovir in Appendix A: Pediatric Antiretroviral Drug Information). Use of protease inhibitors may be associated with hyperglycemia. Hepatic transaminases (alanine aminotransferase and aspartate aminotransferase) increase with many ARV drugs. Bilirubin should be measured prior to starting atazanavir because that drug causes an increase in indirect bilirubin (see Atazanavir in Appendix A: Pediatric Antiretroviral Drug Information). For further details of adverse effects associated with a particular ARV, see Tables 11a-11l in Management of Medication Toxicity or Intolerance.

**Within 1 to 2 Weeks of Initiation of Combination Antiretroviral Therapy**

Within 1 to 2 weeks of initiating therapy, children should be evaluated either in person or by phone to identify clinical adverse effects and to support adherence. Many clinicians plan additional contacts (in person, by telephone, or via email) with children and caregivers to support adherence during the first few weeks of therapy.

**2 to 4 Weeks after Initiation of Combination Antiretroviral Therapy**

While data are limited on which to base an exact recommendation about precise timing, most experts recommend laboratory testing at 2 to 4 weeks (and not more than 8 weeks) after initiation of cART to assess virologic response and laboratory toxicity. The selection of laboratory chemistry tests is regimen-specific (see above). Evaluation of hepatic transaminases is recommended at 2 weeks and 4 weeks for patients starting treatment that includes nevirapine (see Nevirapine in Appendix A: Pediatric Antiretroviral Drug Information). Plasma viral load monitoring is important as a marker of response to cART because a fall in viral load suggests medication adherence, administration of appropriate doses, and viral drug susceptibility. Some experts favor measuring viral load at 2 weeks to ensure that viral load is declining. Because of higher baseline viral load in infants and young children, the decline in viral load after cART initiation may be slower than in adults. A significant decrease in viral load in response to cART should be observed by 4 to 8 weeks of therapy.
Routine Testing for Patients Receiving Combination Antiretroviral Therapy

After the initial phase of cART initiation, regimen adherence, effectiveness (CD4 cell count and percentage and plasma viral load), and toxicities (history, physical, and laboratory testing as above) should be assessed every 3 to 4 months in children receiving cART. Children who develop symptoms of toxicity should have appropriate laboratory evaluations (such as evaluation of serum lactate in a child receiving NRTIs who develops symptoms suspicious for lactic acidosis). If laboratory evidence of toxicity is identified, testing should be performed more frequently until the toxicity resolves.

Testing for Patients Who are Stable on Long-Term Combination Antiretroviral Therapy

Recent studies have critically evaluated the frequency of laboratory monitoring in both adults and children, particularly CD4 cell count and plasma viral load. These studies support less frequent monitoring in stable patients in whom viral suppression has been sustained for at least a year.35-40 The current Adult and Adolescent Guidelines support plasma viral load testing every 6 months for individuals who have

1. CD4 count >350 cells/mm³
2. Consistent virus suppression for more than 2 years.

The Panel finds value in continuing viral load testing every 3 to 4 months to provide enhanced monitoring of adherence or disease progression among children and youth. Some experts monitor CD4 cell count and percentage less frequently (e.g., every 6 to 12 months) in children and youth who are adherent to therapy and have CD4 cell value well above the threshold for opportunistic infection risk, sustained viral suppression, and stable clinical status for more than 2 to 3 years. Some clinicians find value in visits every 3 months even when lab testing is not performed in order to review adherence and update dosing for interim growth.

Testing at the Time of Switching Combination Antiretroviral Therapy

When a switch in regimen is made to simplify cART, labs appropriate to the toxicity profile of the new regimen should be measured at baseline, with follow up including plasma viral load at 4 weeks (and not more than 8 weeks) after the switch, to ensure efficacy of the new regimen. If the regimen is switched because of cART failure (see Recognizing and Managing Antiretroviral Treatment Failure in Management of Children Receiving Antiretroviral Therapy) resistance testing should be performed while a patient is still receiving the failing regimen to optimize the chance of identifying resistance mutations because resistant strains may revert to wild type within a few weeks of stopping ARV drugs (see Antiretroviral Drug-Resistance Testing).

1 See text for details of appropriate tests to send.

2 Readiness for ARV adherence is assessed prior to starting cART. If abacavir is being considered as part of the regimen, send HLA-B*5701 testing prior to initiation of that ARV and choose an alternative ARV if HLA-B*5701 is positive (see Abacavir in Appendix A: Pediatric Antiretroviral Drug Information). Genotype resistance testing is recommended if not already performed (see Antiretroviral Drug-Resistance Testing). Send tests appropriate to the toxicities expected from each patient’s cART regimen and history (see text).

3 If cART is initiated within 30 to 45 days of a pre-therapy lab result, repeat testing may not be necessary.

4 CD4 cell count and percentage can be monitored less frequently (every 6–12 months) in children and youth who are adherent to therapy and have CD4 cell value well above the threshold for opportunistic infection risk, sustained viral suppression, and stable clinical status for more than 2 to 3 years.

5 If lipids have been abnormal in the past, more frequent monitoring might be needed. For patients treated with tenofovir, more frequent urinalysis is considered.

6 When considering starting antiretrovirals with activity against hepatitis B, specifically lamivudine, emtricitabine-, and tenofovir-containing regimens

Key to Acronyms: ARV = antiretroviral, cART = combination antiretroviral therapy, CBC = complete blood count, CD4 = CD4 T lymphocyte

4. Dunn D, Group HIVPPMCS. Short-term risk of disease progression in HIV-1-infected children receiving no

General Considerations

Antiretroviral (ARV) treatment of pediatric HIV infection has steadily improved since the introduction of potent combination drug regimens that effectively suppress viral replication in most patients, resulting in a lower risk of virologic failure due to development of drug resistance. Combination antiretroviral therapy (cART) regimens including at least three drugs from at least two drug classes are recommended; such regimens have been associated with enhanced survival, reduction in opportunistic infections and other complications of HIV infection, improved growth and neurocognitive function, and improved quality of life in children. In the United States and the United Kingdom, significant declines in morbidity, mortality, and hospitalizations have been reported in HIV-infected children between 1994 and 2006, concomitant with increased use of highly active combination regimens. As a result, perinatally HIV-infected children are now living into the third and fourth decades of life, and potentially beyond.

The increased survival of HIV-infected children is associated with challenges in selecting successive new ARV drug regimens. In addition, therapy is associated with short- and long-term toxicities, which can be recognized in childhood or adolescence (see Management of Medication Toxicity or Intolerance).

ARV drug-resistant virus can develop during cART because of poor adherence, subtherapeutic drug levels, a regimen that is not potent, or a combination of these factors which results in incomplete viral suppression. In addition, primary drug resistance may be seen in ARV-naive children who have become infected with a resistant virus. Thus, decisions about when to start therapy (see When to Initiate), what drugs to choose in ARV-naive children (see What to Start) and how to best treat ARV-experienced children remain complex. Whenever possible, decisions regarding the management of pediatric HIV infection should be directed by or made in consultation with a specialist in pediatric and adolescent HIV infection. Treatment of ARV-naive children (when and what to start), when to change therapy, and treatment of ARV-experienced children will be discussed in separate sections of the guidelines.

Several factors need to be considered in making decisions about initiating and changing cART in children, including:

- Severity of HIV disease and risk of disease progression, as determined by age, presence or history of HIV-related illnesses, degree of CD4 T lymphocyte (CD4) immunosuppression, (see Revised Surveillance Case Definition for HIV Infection at http://www.cdc.gov/mmwr/pdf/rr/rr6303.pdf) and level of HIV plasma viremia;
- Availability of appropriate (and palatable) drug formulations and pharmacokinetic (PK) information on appropriate dosing in a child’s age/weight group;
- Potency, complexity (e.g., dosing frequency, food and fluid requirements), and potential short- and long-term adverse effects of the cART regimen;
- Effect of initial regimen choice on later therapeutic options;
- A child’s cART history;
- Presence of ARV drug-resistant virus;
- Presence of comorbidity, such as tuberculosis, hepatitis B or C virus infection, or chronic renal or liver disease, that could affect decisions about drug choice and the timing of initiation of therapy;
- Potential ARV drug interactions with other prescribed, over-the-counter, or complementary/alternative medications taken by a child; and
- The anticipated ability of the caregiver and child to adhere to the regimen.
The following recommendations provide general guidance for decisions related to treatment of HIV-infected children, and flexibility should be exercised according to a child’s individual circumstances. Guidelines for treatment of HIV-infected children are evolving as new data from clinical trials become available. Although prospective, randomized, controlled clinical trials offer the best evidence for formulation of guidelines, most ARV drugs are approved for use in pediatric patients based on efficacy data from clinical trials in adults, with supporting PK and safety data from Phase I/II trials in children. In addition, efficacy has been defined in most adult trials based on surrogate marker data, as opposed to clinical endpoints. For the development of these guidelines, the Panel reviewed relevant clinical trials published in peer-reviewed journals or in abstract form, with attention to data from pediatric populations when available.

**Goals of Antiretroviral Treatment**

Although there was a single case report of a period of prolonged remission in an HIV-infected child treated with a cART regimen initiated at age 30 hours, viremia returned in this child after more than 2 years of undetectable HIV RNA levels following discontinuation of cART. Current cART has not been shown to eradicate HIV infection in perinatally infected infants due to persistence of HIV in CD4 lymphocytes and other cells. Some data suggest that the half-life of intracellular HIV proviral DNA is even longer in infected children than in adults (median 14 months vs. 5–10 months, respectively). Thus, based on currently available data, HIV causes a chronic infection likely requiring treatment for life once a child starts therapy. The goals of cART for HIV-infected children and adolescents include:

- Preventing and reducing HIV-related morbidity and mortality;
- Restoring and/or preserving immune function as reflected by CD4 cell measures;
- Maximally and durably suppressing viral replication;
- Preventing emergence of viral drug-resistance mutations;
- Minimizing drug-related toxicity;
- Maintaining normal physical growth and neurocognitive development;
- Improving quality of life;
- Reducing the risk of sexual transmission to discordant partners in adolescents who are sexually active; and
- Reducing the risk of perinatal transmission in adolescent females who become pregnant.

Strategies to achieve these goals require a complex balance of potentially competing considerations.

**Use and Selection of Combination Antiretroviral Therapy**

The treatment of choice for HIV-infected children is a regimen containing at least three drugs from at least two classes of ARV drugs. The Panel has recommended several preferred and alternative regimens (see What to Start). The most appropriate regimen for an individual child depends on multiple factors as noted above. A regimen that is characterized as an alternative choice may be a preferred regimen for some patients.

**Drug Sequencing and Preservation of Future Treatment Option**

The choice of ARV treatment regimens should include consideration of future treatment options, such as the presence of or potential for drug resistance. Multiple changes in ARV drug regimens can rapidly exhaust treatment options and should be avoided. Appropriate sequencing of drugs for use in initial and second-line therapy can preserve future treatment options and is another strategy to maximize long-term benefit from therapy. Current recommendations for initial therapy are to use two classes of drugs (see What to Start), thereby sparing three classes of drugs for later use.
Maximizing Adherence

As discussed in Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents, poor adherence to prescribed regimens can lead to subtherapeutic levels of ARV medications, which increases the risk of development of drug resistance and likelihood of virologic failure. Issues related to adherence to therapy should be fully assessed, discussed, and addressed with a child’s caregiver and the child (when age appropriate) before the decision to initiate therapy is made. Participation by the caregiver and child in the decision-making process is crucial. Potential problems should be identified and resolved before starting therapy, even if this delays initiation of therapy. In addition, frequent follow-up is important to assess virologic response to therapy, drug intolerance, viral resistance, and adherence. Finally, in patients who experience virologic failure, it is critical to fully assess adherence and possible viral resistance before making changes to the cART regimen.

References

Overview

The decision about when to initiate combination antiretroviral therapy (cART) in asymptomatic HIV-infected older children and adolescents continues to generate controversy among HIV experts. Aggressive therapy in the early stages of HIV infection has the potential to control viral replication before HIV can evolve into diverse and potentially more pathogenic quasispecies. Initiation of therapy at higher CD4 T lymphocyte (CD4) cell counts has been associated with fewer drug resistance mutations at virologic failure in adults. Early therapy also slows immune system destruction and preserves immune function, preventing clinical disease progression. Ongoing viral replication may be associated with persistent inflammation and development of cardiovascular, kidney, and liver disease and malignancy; studies in adults suggest that early control of replication may reduce the occurrence of these non-AIDS complications. Conversely, delaying therapy until later in the course of HIV infection, when clinical or immunologic symptoms appear, may result in reduced evolution of drug-resistant virus due to a lack of drug selection pressure, improved adherence to the therapeutic regimen due to perceived need when the patient becomes symptomatic, and reduced or delayed adverse effects of cART. Because therapy in children is initiated at a young age and will likely be life-long, concerns about adherence and toxicities are particularly important.

The Department of Health and Human Services (HHS) Adult and Adolescent Antiretroviral Guidelines Panel (the Panel) has recommended initiation of therapy for all adults with HIV infection, with the proviso that the strength of the recommendations is dependent on the pre-treatment CD4 count. Randomized clinical trials have provided definitive evidence of benefit with initiation of therapy in adults with CD4 counts 200 to <350 cells/mm³. A secondary analysis of an international randomized trial in adults with CD4 counts between 350 and 550 cells/mm³ versus waiting until the CD4 count dropped below 250 cells/mm³ showed significantly fewer AIDS events and tuberculosis diagnoses when treatment was initiated at a higher CD4 count (median 442 vs. 230 cells/mm³). Observational cohort data have also demonstrated the benefit of treatment in adults with CD4 counts between 350 and 500 cells/mm³ in reducing morbidity and mortality; therefore, adult treatment guidelines recommend initiation of lifelong cART for individuals with CD4 counts 350 to 500 cells/mm³. For adults with CD4 counts >500 cell/mm³, observational data are less conclusive regarding the potential survival benefit of early treatment. The recommendation for initiation of therapy at CD4 counts >500/mm³ in adults is based on accumulating data that untreated HIV infection may be associated with development of many non-AIDS-defining diseases, the availability of more effective cART regimens with improved tolerability, and evidence that effective cART reduces secondary sexual HIV transmission. However, the Panel acknowledges that the amount of data supporting earlier initiation of therapy decreases as the CD4 count increases above 500 cells/mm³, and that concerns remain over the unknown overall benefit, long-term risks, cumulative additional costs, and potential for decreased medication adherence associated with earlier treatment in asymptomatic patients.
### Treatment Recommendations for Initiation of Therapy in Antiretroviral-Naive, HIV-Infected Infants and Children

#### Rating of Recommendations: A = Strong; B = Moderate; C = Optional

#### Rating of Evidence: I = One or more randomized trials in children with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children; II = One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II* = One or more well-designed, nonrandomized trials or observational cohort studies with long-term outcomes; III = One or more nonrandomized trials or cohort studies with clinical outcomes in children from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III* = expert opinion

#### Studies that include children or children and adolescents but not studies limited to postpubertal adolescents

#### Note: Adherence should be assessed and discussed with HIV-infected children and their caregivers before initiation of therapy (AIII).

* Within 1–2 weeks, including an expedited discussion on adherence

* More time can be taken to fully assess and address issues associated with adherence with the caregivers and the child prior to initiating therapy. Patients/caregivers may choose to postpone therapy, and on a case-by-case basis, providers may elect to defer therapy based on clinical and/or psychosocial factors.

* CD4 counts should be confirmed with a second test to meet the treatment criteria before initiation of cART.

* To avoid overinterpretation of temporary blips in viral load (which can occur, for example, during intercurrent illnesses), plasma HIV RNA level >100,000 copies/mL should be confirmed by a second level before initiating cART.

#### Infants Younger Than Age 12 Months

The Children with HIV Early Antiretroviral Therapy (CHER) Trial, a randomized clinical trial in South Africa, demonstrated that initiating triple-drug cART before 12 weeks in asymptomatic perinatally infected infants with normal CD4 percentage (>25%) resulted in a 75% reduction in early mortality, compared with delaying...
treatment until the infants met clinical or immune criteria. Most of the deaths in the infants in the delayed treatment arm occurred in the first 6 months after study entry. A substudy of this trial also found that infants treated early had significantly better gross motor and neurodevelopmental profiles than those in whom therapy was deferred. Because the risk of rapid progression is so high in young infants and based on the data in young infants from the CHER study, the Panel recommends initiating therapy for all infants <12 months regardless of clinical status, CD4 percentage, or viral load (Table 5). Before therapy is initiated, it is important to fully assess, discuss, and address issues associated with adherence with an HIV-infected infant’s caregivers. However, given the high risk of disease progression and mortality in young HIV-infected infants, it is important to expedite this assessment in infants younger than 12 months.

The risk of disease progression is inversely correlated with the age of a child, with the youngest infants at greatest risk of rapid disease progression. Progression to moderate or severe immune suppression is also frequent in older infected infants; by 12 months, approximately 50% of children develop moderate immune suppression and 20% develop severe immune suppression. In the HIV Paediatric Prognostic Markers Collaborative Study meta-analysis, the 1-year risk of AIDS or death was substantially higher in younger children than in older children at any given level of CD4 percentage, particularly for infants younger than <12 months. Unfortunately, although the risk of progression is greatest in the first year of life, the ability to differentiate children at risk of rapid versus slower disease progression by clinical and laboratory parameters is also most limited in young infants. No specific “at-risk” viral or immunologic threshold can be easily identified, and progression of HIV disease and opportunistic infections can occur in young infants with normal CD4 cell counts.

Identification of HIV infection during the first few months of life permits clinicians to initiate cART during the initial phases of primary infection. Data from a number of observational studies in the United States and Europe suggest that infants who receive early treatment are less likely to progress to AIDS or death than those who start therapy later. A study of 195 South African children initiating cART aged <24 months found that infants treated by 6 months achieved target growth milestones more rapidly than children who initiated therapy between 12 and 24 months. Several small studies have demonstrated that, despite the very high levels of viral replication in perinatally infected infants, early initiation of treatment can result in durable viral suppression and normalization of immunologic responses to non-HIV antigens in some infants. In infants with sustained control of plasma viremia, failure to detect extra-chromosomal replication intermediates suggests near-complete control of viral replication. Some of these infants have become HIV seronegative. Although there is a single case report of a period of remission in an HIV-infected child treated with a cART regimen initiated at age 30 hours, discussed below, current cART has not been shown to eradicate HIV infection in perinatally infected infants because of persistence of HIV in CD4 lymphocytes and other cells.

The report of a prolonged remission in an HIV-infected child in Mississippi generated discussion about early initiation of cART in newborn infants with high-risk HIV exposure. This newborn, born to a mother who did not receive antenatal or perinatal cART, was treated with a three-drug cART regimen at ages 30 hours through 18 months, after which cART was discontinued against medical advice. Intensive follow-up evaluations showed no evidence of virologic rebound for more than 2 years following discontinuation of cART, at which time viremia recurred and cART was restarted. This experience has prompted increasing support for initiation of treatment in the first weeks of life, as soon as the diagnosis is made. However, because of limited safety and pharmacokinetic data and experience with antiretroviral (ARV) drugs in infants <2 to 4 weeks, drug and dose selection in this age group is challenging (see What to Start and Specific Issues in Antiretroviral Treatment for Neonates). If early treatment is initiated, the Panel does not recommend empiric treatment interruption.

Virologic suppression may take longer to achieve in young children than in older children or adults. Possible reasons for the slower response in infants include higher virologic set points in young infants, inadequate ARV drug levels, and poor adherence because of the difficulties in administering complex regimens to infants. With currently available drug regimens, rates of viral suppression of 70% to 80% have been reported in HIV-infected infants initiating therapy at <12 months. In a 5-year follow-up study of 40 HIV-infected children who initiated treatment at <6 months, 98% had CD4 percentage >25% and 78% had undetectable viral load with median follow-up of 5.96 years. More rapid viral suppression in young infants may also be
Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

F-4

important in reducing the long-lived HIV reservoir; a study of 17 HIV-infected infants initiating lopinavir/ritonavir-based cART before 6 months demonstrated that time to the first HIV viral load <400 copies/mL was correlated with the size of the long-lived HIV reservoir (i.e., the resting memory CD4 cell pool). In addition, in the Pediatric HIV/AIDS Cohort Study/Adolescent Master Protocol (a cross-sectional study of 144 perinatally infected youth with long term viral suppression) found a lower proviral reservoir in those who achieved vireologic control at <1 year versus 1 to 5 years versus >5 years of age (4.2 vs. 19.4 vs. 70.7 copies/million peripheral blood mononuclear cells, respectively). Information on appropriate drug dosing in infants younger than 3 to 6 months is limited. Hepatic and renal functions are immature in newborns undergoing rapid maturational changes during the first few months of life, which can result in substantial differences in ARV dose requirements between young infants and older children. When drug concentrations are subtherapeutic, either because of inadequate dosing, poor absorption, or incomplete adherence, ARV drug resistance can develop rapidly, particularly in the setting of high levels of viral replication in young infants. Frequent follow-up and continued assessment and support of adherence are especially important when treating young infants (see Adherence). Finally, the possibility of long-term toxicities (e.g., lipodystrophy, dyslipidemia, glucose intolerance, osteopenia, mitochondrial dysfunction) with prolonged therapy is a concern.

Children Aged 1 Year and Older

In general, disease progression is less rapid in children aged ≥1 year, however, children with stage 3-defining opportunistic infections (see Revised Surveillance Case Definition for HIV Infection at http://www.cdc.gov/mmwr/pdf/rr/rr6303.pdf and Table 7) are at high risk of disease progression and death. Given the high risk of disease progression and mortality with severe HIV disease, the Panel recommends urgent treatment (i.e., within 1–2 weeks) for all such children, regardless of immunologic or virologic status. In these cases, the clinical team should expedite a discussion on adherence and provide increased, intensive follow-up in the first few weeks to support the children and families. Children aged ≥1 year who have mild to moderate clinical symptoms (see Table 7) or who are asymptomatic are at lower risk of disease progression than children with more severe clinical symptoms. In these children, more time can be taken to fully assess, discuss and address issues associated with adherence with the caregivers and the children prior to initiating therapy. In asymptomatic children, consideration of CD4 count and viral load may be useful in determining the need for therapy.

In adults, the strength of recommendations to initiate cART in asymptomatic individuals is based primarily on risk of disease progression, as determined by baseline CD4 cell count. In adults, both clinical trial and observational data support initiation of treatment in individuals with CD4 counts <350 cells/mm³. In HIV-infected adults in Haiti, a randomized clinical trial found significant reductions in mortality and morbidity with initiation of treatment when CD4 counts fell to <350 cells/mm³, compared with deferring treatment until CD4 cell counts fell to <200 cells/mm³. In observational data in adults, a collaborative analysis of data from 12 adult cohorts in North America and Europe on 20,379 adults starting treatment between 1995 and 2003, the risk of AIDS or death was significantly less in adults who started treatment with CD4 counts 200 to 350 cells/mm³ compared with those who started therapy at CD4 counts <200 cells/mm³. A prospective observational cohort study of 468 adults found that initiation of cART within 4 months of infection resulted in the highest likelihood and fastest rate of recovery of CD4 counts when compared with initiation between 4 and 12 months or more than 12 months post-infection. Furthermore, starting cART at lower CD4 counts, defined as <500 cells/mm³, as compared with higher CD4 counts, was associated with a significant reduction in CD4 recovery.

The Cochrane Collaboration published a review on the effectiveness of cART in HIV-infected children aged <2 years based on data from published randomized trials of early versus deferred cART. The authors concluded that immediate therapy reduces morbidity and mortality and may improve neurologic outcome, but that data are less compelling in support of universal initiation of treatment between ages 1 and 2 years.

The Pediatric Randomised Early versus Deferred Initiation in Cambodia and Thailand (PREDICT) trial was
designed to investigate the impact on AIDS-free survival and neurodevelopment of deferral of cART in children aged >1 year. This multicenter, open-label trial randomized 300 HIV-infected children aged >1 year (median 6.4 years) to immediate initiation of cART or deferral until the CD4 percentage was <15%. The median baseline CD4 percentage was 19% (IQR 16% to 22%) and 46% of children in the deferred group started cART during the study. AIDS-free survival at week 144 was 98.7% (95% CI 94.7–99.7) in the deferred group and 97.9% (CI 93.7–99.3) in the immediate therapy group (P = 0.6), and immediate cART did not significantly improve neurodevelopmental outcomes. However, because of the low event rate, the study was underpowered to detect a difference between the two groups. This study population likely had a selection bias toward relatively slowly progressive disease because it enrolled children who had survived a median of 6 years without cART. The limited enrollment of children aged <3 years poses restrictions on its value for recommendations in that age group.

A secondary analysis of a randomized controlled trial addresses the comparative efficacy of starting versus deferring treatment at higher CD4 thresholds in HIV-infected adults. The HPTN 052 trial randomized 1763 HIV-serodiscordant couples to initiate ARV treatment either on entry into the study (median CD4 counts of 442 IQR 373–522 cells/mm³) or after a decline in CD4 count to <250 cells/mm³ or with onset of an AIDS-related illness (median CD4 count 230 [IQR 197–249] cells/mm³). New-onset AIDS events and tuberculosis occurred more frequently in the deferred versus early treatment group (P = 0.031 and 0.018, respectively), thus showing a benefit to starting cART early, when the CD4 count is over 400 cells/mm³. Two observational studies in adults—the ART Cohort Collaboration (ART-CC) and North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD)—also suggest a higher rate of progression to AIDS or death in patients deferring treatment until the CD4 count is <350/mm³ compared with patients starting cART at CD4 counts of 351 to 500 cells/mm³. The NA-ACCORD study demonstrated a benefit of starting treatment at CD4 cell counts >500 cell/mm³ compared with starting cART at CD4 cell counts below this threshold; however, the ART-CC cohort found no additional benefit for patients starting cART with CD4 cell counts >450 cells/mm³. In a third observational study of 5,162 patients with CD4 cell counts between 500 and 799 cells/mm³, patients who started cART immediately did not experience a significant reduction in progression to AIDS or death (HR: 1.10, 95% CI: 0.67 to 1.79) or death alone (HR: 1.02, 95% CI: 0.49 to 2.12), compared with those who deferred therapy. There are no similar observational data analyses for HIV-infected children.

In children, the prognostic significance of a specific CD4 percentage or count varies with age. In data from the HIV Paediatric Prognostic Markers Collaborative Study meta-analysis, derived from 3,941 children with 7,297 child-years of follow-up, the risk of mortality or progression to AIDS per 100 child-years is significantly higher for any given CD4 count in children ages 1 to 4 years than in children aged ≥5 years (see Figures A and B and Tables A and B in Appendix C: Supplemental Information). Data from the HIV Paediatric Prognostic Markers Collaborative Study suggest that absolute CD4 cell count is a useful prognostic marker for disease progression in children aged ≥5 years, with risk of progression similar to that observed in adults (see Table B in Appendix C: Supplemental Information). For children ages 1 to <5 years, a similar increase in risk of AIDS or death is seen when CD4 percentage drops below 25% (see Table A in Appendix C: Supplemental Information).

Because the CD4 percentage is more consistent than the naturally declining CD4 cell count in the first years of life, it has been used preferentially to monitor immunologic status in children aged <5 years. However, an analysis of more than 21,000 pairs of CD4 measurements from 3,345 children aged <1 to 16 years in the HIV Paediatric Prognostic Markers Collaborative Study found that CD4 cell counts and percentages were frequently discordant around established World Health Organization (WHO) and the Pediatric European Network for Treatment of AIDS (PENTA) thresholds for initiation of cART (14% and 21%, respectively). Furthermore, CD4 cell counts were found to provide greater prognostic value over CD4 percentage for short-term disease progression for children aged <5 years as well as in older children. For example, the estimated hazard ratio for AIDS or death at the 10th centile of CD4 cell count (compared with the 50th centile) was 2.2 (95% confidence interval [CI]) 1.4, 3.0) for children ages 1 to 2 years versus 1.2 (CI 0.8, 1.6) for CD4 percentage. Recently, the CDC has issued an updated HIV infection staging classification based on age-specific CD4 values, indicating a preference for CD4 count over CD4 percentage in all ages (see Revised

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection
The level of plasma HIV RNA may provide useful information in terms of risk of progression, although its prognostic significance is weaker than CD4 count.\textsuperscript{45} Several studies have shown that children with HIV RNA levels $\geq 100,000$ copies/mL are at high risk of mortality\textsuperscript{48-50} and lower neurocognitive performance;\textsuperscript{51} similar findings have been reported in adults.\textsuperscript{52-54} Similarly, in the HIV Paediatric Prognostic Markers Collaborative Study meta-analysis, the 1-year risk of progression to AIDS or death rose sharply for children aged $>1$ year when HIV RNA levels were $\geq 100,000$ copies/mL (see Figures D and E and Table A in Appendix C: Supplemental Information).\textsuperscript{45} For example, the estimated 1-year risk of death was 2 to 3 times higher in children with plasma HIV RNA 100,000 copies/mL compared with 10,000 copies/mL and 8 to 10 times higher with plasma HIV RNA $>1,000,000$ copies/mL. Therefore, the Panel recommends that children of all ages with HIV RNA levels $>100,000$ copies/mL initiate cART.

As with data in adults, data from pediatric studies suggest that improvement in immunologic parameters is better in children when treatment is initiated at higher CD4 percentage/count levels.\textsuperscript{31,55-60} In a study of 1,236 perinatally infected children in the United States, only 36\% of those who started treatment with CD4 percentage $<15\%$ and 59\% of those starting with CD4 percentage $15\%$ to $24\%$ achieved CD4 percentage $>25\%$ after 5 years of therapy.\textsuperscript{61} Younger age at initiation of therapy has also been associated with improved immune response and with more rapid growth reconstitution.\textsuperscript{22,31,55,61,62} In addition, the PREDICT Study demonstrated improved height z-scores in the early treatment arm compared with no improvement in the deferred arm.\textsuperscript{43}

Given that disease progression in children aged $\geq 5$ years is similar to that in adults,\textsuperscript{46} and observational data in adults show decreased risk of mortality with initiation of therapy when CD4 cell count is $<500$ cells/mm$^3$,\textsuperscript{10,11} most experts feel that recommendations for asymptomatic children in this age range should be similar to those for adults. However, there are no conclusive pediatric data to address the optimal CD4 cell count threshold for initiation of therapy in older children; additional research studies are needed to answer this question in children more definitively. The Panel has moved to endorse initiating cART in all HIV-infected adults regardless of CD4 cell count, using varying strengths of evidence to support different CD4 cell count thresholds\textsuperscript{7} and incorporating compelling data demonstrating that cART is effective in preventing secondary transmission of HIV. However, prevention of sexual transmission of HIV is not a significant consideration for children aged $<13$ years. Comparative studies on the impact of treatment versus treatment delay at specific higher CD4 cell counts have not been performed in children, and observational adult studies have produced conflicting results.\textsuperscript{10,11,14} Drug choices are more limited in children than in adults and adequate data to address the potential long-term toxicities of prolonged cART in a developing child are not yet available. Some studies have shown that a small proportion of perinatally infected children may be long-term nonprogressors, with no immunologic or clinical progression by age 10 years despite receiving no cART.\textsuperscript{63-65} Medication adherence is the core requirement for successful virologic control, but achieving consistent adherence in childhood is often challenging.\textsuperscript{66} Incomplete adherence leads to the selection of viral resistance mutations but forced administration of ARVs to children may result in treatment aversion or fatigue, which occurs among many perinatally infected children during adolescence.\textsuperscript{67} The relative benefits of initiating cART in asymptomatic children with low viral burdens and high CD4 cell counts must be weighed against these potential risks.

The Panel recommends that cART be urgently initiated in all children younger than aged 12 months, and in those aged 12 months or older who have Centers for Disease Control and Prevention (CDC) Stage 3-defining opportunistic illnesses or Stage 3 CD4 counts (Tables 6 and 7).

The Panel also recommends that children aged 12 months or older with the following findings initiate cART:

- Moderate HIV-related symptoms (Table 7), regardless of CD4 count;
- HIV RNA $>100,000$ copies/mL, regardless of CD4 count or symptoms;
- CDC Stage 2 CD4 counts (Table 6), with the strength of the recommendation differing based on age and CD4 count.

The evidence for this recommendation is strongest for children with CD4 cell counts $<350$ cells/mm$^3$. For
children with CD4 cell counts 350 to 500 cells/mm³, the recommendation is based on observational data in adults, hence the evidence base is not as strong; this recommendation should not prohibit research studies in children designed to answer this question more definitively.

The Panel also recommends consideration of treatment for all children aged 12 months or older with no or mild symptoms and CDC Stage 1 CD4 counts (Tables 6 and 7), although the strength of recommendation is lower because of limited data.

Patients/caregivers may choose to postpone therapy, and, on a case-by-case basis, providers may elect to defer therapy based on clinical and/or psychosocial factors. Note that the Panel’s recommendations which permit optional deferral of therapy for healthy children older than 1 year are different from the 2013 WHO guidelines, which recommend initiation of therapy for all children younger than 5 years, reflecting different approaches in resource-limited settings.

In general, except in infants younger than age 12 months and children with advanced HIV infection, cART does not need to be started urgently (i.e., within 1–2 weeks). Before initiating therapy, it is important to take time to educate caregivers (and children, as appropriate) about regimen adherence and to anticipate and resolve any barriers that might diminish adherence. This is particularly true for children age 5 years and older, given their lower risk of disease progression and the higher CD4 cell count threshold now recommended for initiating therapy.

If therapy is deferred, the health care provider should closely monitor a child’s virologic, immunologic, and clinical status every 3 to 4 months (see Clinical and Laboratory Monitoring). Factors to consider in deciding when to initiate therapy in children in whom treatment was deferred include:

- Increasing HIV RNA levels (e.g., HIV RNA levels approaching 100,000 copies/mL);
- CD4 count or percentage values approaching the age-related threshold for treatment;
- Development of clinical symptoms; and
- The ability of caregiver and child to adhere to the prescribed regimen.

**Table 5. Indications for Initiation of Antiretroviral Therapy in HIV-Infected Children** (page 1 of 2)

Table 5 provides general guidance rather than absolute recommendations for individual patients. Factors to be considered in decisions about initiation of therapy include risk of disease progression as determined by CD4 percentage or count and plasma HIV RNA copy number, the potential benefits and risks of therapy, and the ability of the caregiver to adhere to administration of the therapeutic regimen. Urgent treatment should be initiated within 1 to 2 weeks, including an expedited discussion on adherence. In non-urgent settings, more time can be taken to fully assess and address issues associated with adherence with the caregivers and the child prior to initiating therapy. Patients/caregivers may choose to postpone therapy and, on a case-by-case basis, providers may elect to defer therapy based on clinical and/or psychosocial factors.

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = data from randomized controlled trials in children; I* = data from randomized trials in adults with accompanying data in children from nonrandomized trials or observational cohort studies with long-term clinical outcomes; II: data from well-designed nonrandomized trials or observational cohort studies in children with long-term clinical outcomes; II* = data from well-designed nonrandomized trials or observational cohort studies in adults with long-term clinical outcomes with accompanying data in children from smaller non-randomized trials or cohort studies with clinical outcomes data; III = Expert opinion

- Children in whom cART is deferred need close follow-up. Factors to consider in deciding when to initiate therapy in children in whom treatment was deferred include:
  - CD4 cell count or percentage values approaching the age-related threshold for treatment;
  - Development of clinical symptoms; and
  - The ability of caregiver and child to adhere to the prescribed regimen.

- To avoid overinterpretation of temporary blips in viral load (which can occur during intercurrent illnesses, for example), plasma HIV RNA level >100,000 copies/mL should be confirmed by a second level before initiating cART.

- Laboratory data should be confirmed with a second test to meet the treatment criteria before initiation of cART.

<sup>a</sup> The stage is based primarily on the CD4 count; the CD4 count takes precedence over the CD4 percentage, and the percentage is considered only if the count is missing. If a Stage 3-defining opportunistic illness has been diagnosed (Table 6), then the stage is 3 regardless of CD4 test results.

### Table 7: HIV-Related Symptoms  (page 1 of 2)

#### Mild HIV-Related Symptoms

Children with two or more of the conditions listed but none of the conditions listed in Moderate Symptoms category

- Lymphadenopathy (≥0.5 cm at more than 2 sites; bilateral at 1 site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory tract infection, sinusitis, or otitis media

#### Moderate HIV-Related Symptoms

- Anemia (hemoglobin <8 g/dL [<80 g/L]), neutropenia (white blood cell count <1,000/μL [<1.0 × 10^9/L]), and/or thrombocytopenia (platelet count <100 × 10^3/μL [<100 × 10^9/L]) persisting for ≥30 days
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal (thrush), persisting (>2 months) in children older than age 6 months
- Cardiomyopathy
- Cytomegalovirus infection, with onset before 1 month
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus stomatitis, recurrent (>2 episodes within 1 year)
- Herpes simplex virus bronchitis, pneumonitis, or esophagitis with onset before 1 month
- Herpes zoster (shingles) involving at least 2 distinct episodes or more than 1 dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Persistent fever (lasting >1 month)
- Toxoplasmosis, onset before 1 month
- Varicella, disseminated (complicated chickenpox)

#### Stage-3-Defining Opportunistic Illnesses In HIV Infection

- Bacterial infections, multiple or recurrent
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy attributed to HIV
- HSV: chronic ulcers (>1 month duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month duration)
- Kaposi sarcoma
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
Stage-3-Defining Opportunistic Illnesses In HIV Infection, continued

- **Mycobacterium avium** complex or **Mycobacterium kansasii**, disseminated or extrapulmonary
- **Mycobacterium tuberculosis** of any site, pulmonary, disseminated, or extrapulmonary
- **Mycobacterium**, other species or unidentified species, disseminated or extrapulmonary
- **Pneumocystis jirovecii** (previously known as **Pneumocystis carinii** pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- Salmonella septicemia, recurrent
- Toxoplasmosis of brain, onset at age >1 month
- Wasting syndrome attributed to HIV

* Only among children aged <6 years.
* Only among adults, adolescents, and children aged ≥6 years.

Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references:

- Centers for Disease Control and Prevention. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR*. 1994;43(No. RR-12).

What to Start: Regimens Recommended for Initial Therapy of Antiretroviral-Naive Children  
(Last updated April 27, 2015; last reviewed April 27, 2015)

Panel’s Recommendations

- Selection of an initial regimen should be individualized based on a number of factors including characteristics of the proposed regimen, patient characteristics, and results of viral resistance testing (AIII).
- The Panel recommends initiating combination antiretroviral therapy (cART) in treatment-naive children using one of the following preferred agents plus a dual-nucleoside/nucleotide reverse transcriptase inhibitor backbone combination:
  - For neonates/infants aged ≥42 weeks postmenstrual and ≥14 days postnatal and children <3 years: lopinavir/ritonavir (AI);
  - For children aged 3 years to <6 years: efavirenz or lopinavir/ritonavir (AI*);
  - For children aged ≥6 years: atazanavir/ritonavir or efavirenz or lopinavir/ritonavir (AI*).
- The Panel recommends the following preferred dual-nucleoside reverse transcriptase inhibitor backbone combinations:
  - For infants <3 months: zidovudine plus (lamivudine or emtricitabine) (AI*);
  - For children aged ≥3 months: abacavir plus (lamivudine or emtricitabine) (AI) or zidovudine plus (lamivudine or emtricitabine) (AI*):
    - HLA-B*5701 genetic testing should be performed before initiating abacavir-based therapy, and abacavir should not be given to a child who tests positive for HLA-B*5701 (AII*);
  - For children aged ≥12 years: abacavir plus lamivudine or plus emtricitabine (AI).
  - For adolescents at Tanner Stage 4 or 5: abacavir plus lamivudine or plus emtricitabine (AI) or tenofovir disoproxil fumarate plus lamivudine or plus emtricitabine (AI*).
- Table 8 provides a list of Panel-recommended alternative and acceptable regimens.
- For infants aged <42 weeks postmenstrual or <14 days postnatal, data are currently inadequate to provide recommended dosing to allow the formulation of an effective, complete cART regimen (see Specific Issues in Antiretroviral Therapy in Newborn Infants with HIV Infection).
- Both emtricitabine and lamivudine, and tenofovir disoproxil fumarate have antiviral activity and efficacy against hepatitis B. For a comprehensive review of this topic, and hepatitis C and tuberculosis during HIV coinfection, the reader should access the Pediatric Opportunistic Infections Guidelines.

Rating of Recommendations: A = Strong, B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

Criteria Used for Recommendations

In general, the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel)’s recommendations are based on reviews of pediatric and adult clinical trial data published in peer-reviewed journals (the Panel may also review data prepared by manufacturers for Food and Drug Administration [FDA] review and data presented in abstract format at major scientific meetings). Few randomized, Phase III clinical trials of combination antiretroviral therapy (cART) in pediatric patients exist that provide direct comparison of different treatment regimens. Most pediatric drug data come from Phase I/II safety and pharmacokinetic (PK) trials and non-randomized, open-label studies. In general, even in studies in adults, assessment of drug efficacy and potency is primarily based on surrogate marker endpoints, such as CD4 T lymphocyte (CD4) cell count and HIV RNA levels. The Panel continually modifies...
recommendations on optimal initial therapy for children as new data become available, new therapies or drug formulations are developed, and additional toxicities are recognized.

Information considered by the Panel for recommending specific drugs or regimens includes:

- Data demonstrating durable viral suppression, immunologic improvement, and clinical improvement (when such data are available) with the regimen, preferably in children as well as adults;
- The extent of pediatric experience with the particular drug or regimen;
- Incidence and types of short- and long-term drug toxicity with the regimen, with special attention to toxicity reported in children;
- Availability and acceptability of formulations appropriate for pediatric use, including palatability, ease of preparation (e.g., powders), volume of syrups, and pill size/number of pills;
- Dosing frequency and food and fluid requirements; and
- Potential for drug interactions with other medications.

The Panel classifies recommended drugs or drug combinations into one of several categories as follows:

- **Preferred:** Drugs or drug combinations are designated as *preferred* for use in treatment-naive children when clinical trial data in children or, more often, in adults have demonstrated optimal and durable efficacy with acceptable toxicity and ease of use, and pediatric studies demonstrate that safety and efficacy are suggested using surrogate markers; additional considerations are listed above.
- **Alternative:** Drugs or drug combinations are designated as *alternatives* for initial therapy when clinical trial data in children or adults show efficacy but there are disadvantages compared with preferred regimens in terms of more limited experience in children; the extent of antiviral efficacy or durability is less well defined in children or less than a preferred regimen in adults; there are specific toxicity concerns; or there are dosing, formulation, administration, or interaction issues for that drug or regimen.
- **Use in Special Circumstances:** Some drugs or drug combinations are recommended for use as initial therapy only in special circumstances when preferred or alternative drugs cannot be used.

### Factors to Consider When Selecting an Initial Regimen

A cART regimen for children should generally consist of two nucleoside reverse transcriptase inhibitors (NRTIs) plus one active drug from the following classes: non-nucleoside reverse transcriptase inhibitor (NNRTI) or protease inhibitor (PI), generally boosted with low-dose ritonavir. Although integrase strand transfer inhibitors (INSTIs) or CCR5 antagonists may be considered for first-line treatment of adults, there are insufficient data to recommend these agents as preferred agents for initial therapy in children and adolescents at this time. Choice of a regimen should be individualized based on a number of factors including characteristics of the proposed regimen, patient characteristics, and results of viral resistance testing. Advantages and disadvantages of each class-based regimen are delineated in detail in the sections that follow and in Table 9. In addition, because cART will most likely need to be administered lifelong, considerations related to the choice of initial antiretroviral (ARV) regimen should also include an understanding of barriers to adherence, including the complexity of schedules and food requirements for different regimens, differing formulations, palatability problems, and potential limitations in subsequent treatment options, should resistance develop. Treatment should only be initiated after assessment and counseling of caregivers about adherence to therapy.

### Choice of Non-Nucleoside Reverse Transcriptase Inhibitor-Based versus Protease Inhibitor-Based Initial Regimens

Preferred regimens for initial therapy include both NNRTI- and PI-based regimens. The selection of a NNRTI- or PI-based regimen should be based on patient characteristics, especially age, and preferences, results of viral drug resistance testing, and information cited below.
Clinical trial data in children provide some guidance for choosing between a NNRTI-based regimen and a PI-based regimen for initial therapy. The P1060 study compared a nevirapine-based regimen to a lopinavir-based regimen in HIV-infected infants and children (in 6 African countries and India) aged 2 months to 35 months. Infants and children in this study were stratified at entry based on prior maternal or infant exposure to peripartum single-dose nevirapine prophylaxis or no exposure, and randomized to receive either zidovudine, lamivudine, and nevirapine or zidovudine, lamivudine, and lopinavir/ritonavir (lopinavir boosted with low-dose ritonavir). Median age was 0.7 years in the single-dose nevirapine-exposed and 1.7 years in the nevirapine-unexposed children. Among infants and children with prior exposure to nevirapine, 39.6% of children in the nevirapine group reached a study endpoint of death, virologic failure, or toxicity by Week 24 compared with 21.7% of children in the lopinavir/ritonavir group. Among infants and children with no prior nevirapine exposure, 40.1% of children treated with nevirapine met a study endpoint after 24 weeks in the study compared with 18.4% of children who received lopinavir/ritonavir. Based on these data, a PI-based regimen containing lopinavir/ritonavir is the preferred initial regimen for HIV-infected children aged <3 years.

A comparison of a PI-based regimen and a NNRTI-based regimen was also undertaken in HIV-infected treatment-naive children aged 30 days to <18 years in PENPACT-1 (PENTA 9/PACTG 390) (the study did not dictate the specific NNRTI or PI drug initiated). In the PI-based group, 49% of children received lopinavir/ritonavir and 48% received nelfinavir; in the NNRTI-based group, 61% of children received efavirenz and 38% received nevirapine. Efavirenz was recommended only for children aged >3 years. After 4 years of follow-up, 73% of children randomized to PI-based therapy and 70% randomized to NNRTI-based therapy remained on their initial cART regimen. In both groups, 82% of children had viral loads <400 copies/mL, suggesting that selection of a NNRTI or a PI did not influence outcome. Although the age of participants overlapped somewhat between P1060 and PENPACT-1 (in PENPACT-1, the lowest quartile was aged <2.8 years), PENPACT-1 generally enrolled older children.

Data from PROMOTE-pediatrics trial also demonstrated comparable virologic efficacy among children randomized to receive either a NNRTI or lopinavir/ritonavir-based cART. Children were aged 2 months to <6 years, with a median of 3.1 years (intermediate between P1060 and PENPACT 1). Children had no perinatal exposure to nevirapine and could be cART-naive or currently receiving cART with HIV RNA level <400 copies/mL at enrollment. In the NNRTI arm, children aged <3 years received nevirapine and those aged >3 years primarily received efavirenz. Among 185 children randomized to lopinavir/ritonavir- (n = 91) or NNRTI- (n = 92) based cART, the proportion with HIV RNA level <400 copies/mL at 48 weeks was 80% in the lopinavir/ritonavir arm versus 76% in the NNRTI-arm, a difference of 4% (95% CI: -9% to +17%).

With regard to virologic suppression, the results of the P1060 study suggest that a PI-based regimen containing lopinavir/ritonavir should be the preferred initial regimen for children aged <3 years. However, in both single-dose nevirapine-exposed and nevirapine-unexposed children in the P1060 study, participants receiving the nevirapine-based regimen demonstrated better immunologic response and growth than those receiving a lopinavir/ritonavir-based regimen, although these differences did not achieve statistical significance. Similarly, in the NEVEREST study, children switched to a nevirapine regimen showed better immune and growth responses than those continuing a lopinavir/ritonavir regimen. Based on these findings, the potential for improved lipid profiles with nevirapine use, and the poor palatability of liquid lopinavir/ritonavir, liquid nevirapine remains an acceptable alternative for infants who were not exposed to peripartum single-dose nevirapine or infant nevirapine prophylaxis and who cannot tolerate lopinavir/ritonavir. In children aged ≥3 years, either a NNRTI-based or a PI-based regimen is acceptable.

**Non-Nucleoside Reverse Transcriptase Inhibitor-Based Regimens (One Non-Nucleoside Reverse Transcriptase Inhibitor plus Two-Nucleoside Reverse Transcriptase Inhibitor Backbone)**

**Summary: Non-Nucleoside Reverse Transcriptase Inhibitor-Based Regimens**

Efavirenz (aged ≥3 months), etravirine (aged ≥6 months) and nevirapine (aged ≥15 days) have an FDA-
approved pediatric indication for treatment of HIV infection. In the United States, nevirapine is the only NNRTI available in a liquid formulation. Efavirenz capsules can be opened and sprinkled on age-appropriate food. This administration procedure has been approved by the FDA for use in children as young as age 3 months who weigh at least 3.5 kg. However, at this time, there are concerns regarding variable PK of the drug in the very young and the committee does not currently endorse its use for infants and children aged 3 months to 3 years at this time. Additional data about the PK in children in this age group are awaited.

Advantages and disadvantages of different NNRTI drugs are delineated in Table 9. Use of NNRTIs as initial therapy preserves the PI class for future use and confers lower risk of dyslipidemia and fat maldistribution than use of some agents in the PI class. In addition, for children taking solid formulations, NNRTI-based regimens generally have a lower pill burden than PI-based regimens. The major disadvantages of the current NNRTI drugs FDA-approved for use in children are that a single viral mutation can confer high-level drug resistance to nevirapine and efavirenz, and cross resistance to other NNRTIs is common. Rare but serious and potentially life-threatening skin and hepatic toxicity can occur with all NNRTI drugs, but is most frequent with nevirapine, at least in HIV-infected adults. Like PIs, NNRTIs have the potential to interact with other drugs also metabolized via hepatic enzymes; however, these drug interactions are less frequent with NNRTIs than with boosted PI regimens.

Efavirenz, in combination with two NRTIs, is the preferred NNRTI for initial therapy of children aged ≥3 years based on clinical trial experience in adults and children. Nevirapine is considered as a component of an alternative NNRTI-based regimen because of its association with the rare occurrence of significant hypersensitivity reactions (HSRs), including Stevens-Johnson syndrome, rare but potentially life-threatening hepatitis,7,8 and conflicting data about virologic efficacy compared to preferred regimens.

Currently, data are insufficient to recommend etravirine or rilpivirine-based regimens as initial therapy in children. Etravirine is licensed for management of treatment-experienced adults and children aged ≥6 years and rilpivirine is licensed only for adults.

Preferred Non-Nucleoside Reverse Transcriptase Inhibitors

Efavirenz as Preferred Non-Nucleoside Reverse Transcriptase Inhibitor (For Children Aged ≥3 Years) (AI*)

In clinical trials in HIV-infected adults, efavirenz in combination with two NRTIs has been associated with excellent virologic response. Efavirenz-based regimens have proven virologically superior or non-inferior to a variety of regimens including those containing lopinavir/ritonavir, nevirapine, rilpivirine, atazanavir, elvitegravir, raltegravir, and maraviroc.9-16

Efavirenz in combination with two NRTIs or with a NRTI and a PI has been studied in HIV-infected children17-23 with results comparable to those seen in adults. For children aged ≥3 years who are unable to swallow pills, efavirenz capsules can be opened and sprinkled on age-appropriate food. Bioequivalence data based on bioavailability and PK support this option.24

The major limitations of efavirenz are central nervous system (CNS) side effects in both children and adults; reported adverse effects include fatigue, poor sleeping patterns, vivid dreams, poor concentration, agitation, depression, and suicidal ideation. Although in most patients this toxicity is transient, in some, the symptoms may persist or occur months after initiating efavirenz. In several studies, the incidence of such adverse effects was correlated with efavirenz plasma concentrations and the occurrence was more frequent in adults with higher levels of drug.25-28 The ENCORE1 study in adults has demonstrated that a dose of 400 mg of efavirenz is associated with fewer adverse events but non-inferior virologic response when compared with the recommended 600-mg dose of efavirenz in adults.29 In patients with pre-existing psychiatric conditions, efavirenz should be used cautiously for initial therapy. Rash may also occur with efavirenz treatment; it is generally mild and transient but appears to be more common in children than adults.21,23 In addition, first-trimester exposure to efavirenz is potentially teratogenic (see Appendix A: Pediatric Antiretroviral Drug Information for detailed information). Although emerging information about the use of efavirenz in
pregnancy is reassuring, alternative regimens that do not include efavirenz should be strongly considered in adolescent females who are trying to conceive or who are not using effective and consistent contraception, because of the potential for teratogenicity with first-trimester efavirenz exposure, assuming these alternative regimens are acceptable to the provider and will not compromise the woman’s health (BIII).

**Alternative Non-Nucleoside Reverse Transcriptase Inhibitors**

**Nevirapine as Alternative Non-Nucleoside Reverse Transcriptase Inhibitor (AI)**

Nevirapine has extensive clinical and safety experience in HIV-infected children and has shown ARV efficacy in a variety of combination regimens (see Appendix A: Pediatric Antiretroviral Drug Information for detailed information). Nevirapine in combination with two NRTIs or with a NRTI and a PI has been studied in HIV-infected children.

Randomized clinical trials in adults have not demonstrated virologic inferiority for a nevirapine-based regimen compared to either efavirenz or atazanavir-based regimens.

Randomized clinical trials in children have demonstrated conflicting results. In the P1060 trial of children aged <3 years, a nevirapine-based regimen was less effective compared to a lopinavir/ritonavir regimen, regardless of prior history of maternal nevirapine exposure. In PENPACT-1 and PROMOTE-pediatrics, there was no difference in virologic suppression between NNRTI-based and PI-based regimens (see Choice of NNRTI- Versus PI-Based Initial Regimens). However, interpretation of these studies is complicated by the fact that the children in P1060 were younger than those in PROMOTE-pediatrics and PENPACT-1. Furthermore, efavirenz was allowed in PROMOTE-pediatrics and PENPACT-1 and was preferentially prescribed to older children. Comparisons of a nevirapine-based regimen and an efavirenz-based regimen in children in non-randomized studies have suggested that efavirenz is more effective but it is usually used in older children.

In addition to concerns about virologic efficacy, adult randomized clinical trials have demonstrated higher rates of toxicity and drug discontinuation in the nevirapine arms. Data in adults indicate that symptomatic hepatic toxicity is more frequent in individuals with higher CD4 cell counts and in women, particularly women with CD4 cell counts >250 cells/mm$^3$ and men with CD4 cell counts >400 cells/mm$^3$. In the published literature, hepatic toxicity appears to be less frequent in children receiving chronic nevirapine therapy than in adults. Although there is limited evidence in children of hepatic toxicity associated with CD4 cell count, overall toxicity has been reported to be more frequent among children with CD4 percentage ≥15% at therapy initiation. The safety of substituting efavirenz for nevirapine in patients who have experienced nevirapine-associated hepatic toxicity is unknown. Efavirenz use in this situation has been well tolerated in the very limited number of patients in whom it has been reported, but this substitution should be attempted with caution.

Nevirapine-based regimens are considered an alternative rather than the preferred NNRTI in children aged ≥3 years because of the greater potential for toxicity and possibly increased risk of virologic failure. In children aged <3 years, nevirapine is considered an alternative because of increased risk of virologic failure compared to a PI lopinavir/ritonavir regimen.

Nevirapine should not be used as part of an initial therapy regimen in postpubertal adolescent girls with CD4 cell counts >250/mm$^3$ because of the increased risk of symptomatic hepatic toxicity, unless the benefit clearly outweighs the risk. Nevirapine also should be used with caution in children with elevated pretreatment liver function tests.

**Protease Inhibitor-Based Regimens (Protease Inhibitors [Boosted or Unboosted] plus Two-Nucleoside Reverse Transcriptase Inhibitor Backbone)**

**Summary: Protease Inhibitor-Based Regimens**

Advantages of PI-based regimens include excellent virologic potency, high barrier for development of drug resistance (requires multiple mutations), and sparing of the NNRTI drug class. However, because PIs are
metabolized via hepatic enzymes, the drugs have potential for multiple drug interactions. They may also be associated with metabolic complications such as dyslipidemia, fat maldistribution, and insulin resistance. Factors to consider in selecting a PI-based regimen for treatment-naive children include virologic potency, dosing frequency, pill burden, food or fluid requirements, availability of palatable pediatric formulations, drug interaction profile, toxicity profile (particularly related to metabolic complications), age of the child, and availability of data in children. (Table 9 lists the advantages and disadvantages of PIs. See Appendix A: Pediatric Antiretroviral Drug Information for detailed pediatric information on each drug.)

Ritonavir is a potent inhibitor of the cytochrome P450 3A4 (CYP3A4) isoenzyme and can be used in low doses as a PK booster when co-administered with some PIs, increasing drug exposure by prolonging the half-life of the boosted PI. Currently only lopinavir/ritonavir is available as a co-formulated product. When ritonavir is used as a PI booster with other PIs, two agents must be administered. In addition, the use of low-dose ritonavir increases the potential for hyperlipidemia and drug-drug interactions.

The Panel recommends either atazanavir with low-dose ritonavir or co-formulated lopinavir/ritonavir as the preferred PI for initial therapy in children based on virologic potency in adult and pediatric studies, high barrier to development of drug resistance, excellent toxicity profile in adults and children, availability of appropriate dosing information, and experience as initial therapy in both resource-rich and resource-limited areas. Darunavir/ritonavir is considered an alternative PI regimen. Several regimens including unboosted atazanavir in adolescents aged ≥13 years, fosamprenavir/ritonavir in children aged ≥6 months, and nelfinavir are considered appropriate for use in special circumstances when preferred and alternative drugs are not available or are not tolerated.

### Preferred Protease Inhibitors

**Atazanavir with Low-Dose Ritonavir as Preferred Protease Inhibitor (for Children ≥6 Years) (AI*)**

Atazanavir is a once-daily PI that was approved by the FDA in March 2008 for use in children aged ≥6 years. Approval was extended in 2014 for use in infants and children aged ≥3 months and weighing ≥10 kg. It has efficacy equivalent to efavirenz-based and lopinavir/ritonavir-based combination therapy when given in combination with two NRTIs in treatment-naive adults. Seventy-three percent of 48 treatment-naive South African children achieved viral load <400 copies/mL by 48 weeks when given atazanavir with or without low-dose ritonavir in combination with 2 NRTIs. Among 43 treatment-naive children aged 6 to 18 years in IMPAACT/PACTG P1020A who received the capsule formulation of atazanavir with or without ritonavir, 51% and 47% achieved viral load <400 copies/mL and <50 copies/mL, respectively, by 96 weeks. When given with low-dose ritonavir boosting, atazanavir achieves enhanced concentrations compared with the unboosted drug in adults and children aged ≥6 years and in ARV-naive adults, appears to be associated with fewer PI-resistance mutations at virologic failure compared with atazanavir given without ritonavir boosting. The main adverse effect associated with atazanavir/ritonavir is indirect hyperbilirubinemia, with or without jaundice or scleral icterus, but without concomitant hepatic transaminase elevations. Although atazanavir is associated with fewer lipid abnormalities than other PIs, lipid levels are higher with low-dose ritonavir boosting than with atazanavir alone. Although atazanavir with low-dose ritonavir is approved for use in infants as young as 3 months, the Panel does not endorse usage as a preferred regimen in infants and children younger than 6 years due to lack of experience and concern about efficacy. Efficacy studies of atazanavir are ongoing in infants and children aged <6 years.

**Lopinavir with Low-Dose Ritonavir as Preferred Protease Inhibitor (for Infants with a Postmenstrual Aged ≥42 Weeks and Postnatal Age ≥14 Days) (AI)**

In clinical trials of treatment-naive adults, regimens containing lopinavir/ritonavir plus 2 NRTIs have been demonstrated to be comparable to a variety of other regimens including atazanavir, darunavir (at 48 weeks), fosamprenavir, saquinavir/ritonavir, and efavirenz. Lopinavir/ritonavir was demonstrated to have superior virologic activity when compared to nelfinavir. Lopinavir/ritonavir has been studied in both ARV-naive and ARV-experienced children and has demonstrated durable virologic activity and low toxicity (see
Appendix A: Pediatric Antiretroviral Drug Information for detailed information). In addition, dosing and efficacy data in infants as young as age 25 days are available. Post-marketing reports of lopinavir/ritonavir-associated cardiac toxicity (including complete atrioventricular block, bradycardia, and cardiomyopathy), lactic acidosis, acute renal failure, CNS depression, and respiratory complications leading to death have been reported, predominantly in preterm neonates. These reports have resulted in a change in lopinavir/ritonavir labeling including a recommendation to not administer the combination to neonates until they reach a postmenstrual age (first day of the mother’s last menstrual period to birth plus the time elapsed after birth) of 42 weeks and a postnatal age of at least 14 days. In addition, although once-daily lopinavir/ritonavir is FDA-approved for initial therapy in adults, PK data in children do not support a recommendation for once-daily dosing in children. A recent study of 173 virologically suppressed children (median age 11 years) on twice-daily lopinavir/ritonavir were randomized to continue twice daily dosing or change to once-daily dosing. At 48 weeks, non-inferiority for viral load suppression was not demonstrated and lopinavir drug exposure was lower among participants with once-daily dosing. These results suggest that lopinavir/ritonavir should only be administered twice daily in children.

Alternative Protease Inhibitors

Atazanavir with Low-Dose Ritonavir as Alternative Protease Inhibitor (for Children ≥3 Months and <6 Years Who Weigh >10 kg) (AI*)

Atazanavir in a powder formulation to be administered once daily with liquid low-dose ritonavir was approved by the FDA in 2014 for use in infants and children aged ≥3 months and weighing ≥10 kg based on findings of two open-label clinical trials, PRINCE I and PRINCE II. Sixty-five infants and children weighing between 10 and 25 kg were studied. Using a weight band approach for determining dose, PK targets were met. The drug was well tolerated and among 41 naive infants and children, 27 (66%) achieved HIV RNA levels <50 copies at week 48. Because of the limited experience with this agent in younger children, the Panel recommends atazanavir with low-dose ritonavir as alternative PI therapy in infants and children aged >3 months and weighing between 10 and 25 kg.

Darunavir with Low-Dose Ritonavir Administered Once Daily as Alternative Protease Inhibitor (for Children Aged ≥12 Years) or Twice Daily (for Children Aged ≥3 to 12 Years) (AI*)

Darunavir combined with low-dose ritonavir is FDA-approved for ARV-naive and -experienced adults and for ARV-naive and -experienced children aged ≥3 years. In a randomized, open-label trial in adults, darunavir/ritonavir (800/100 mg once daily) was found to be non-inferior to lopinavir/ritonavir (once or twice daily) when both boosted PIs were administered in combination with tenofovir disoproxil fumarate (tenofovir)/emtricitabine. Adverse events were also less common in the darunavir/ritonavir group (P < 0.01). Unfortunately, there is limited information about the use of darunavir combined with low-dose ritonavir as part of an initial therapy regimen for HIV-infected children. To date the only clinical trial of darunavir with low-dose ritonavir as initial therapy is a study of once-daily darunavir/ritonavir in treatment-naive adolescents aged 12 to 18 years (mean age, 14.6 years). After 24 weeks of treatment, 11 of 12 participants had HIV-1 RNA <50 copies/mL and the agents were well tolerated. Data in treatment-experienced children have also demonstrated that the regimen is effective and well-tolerated. In a study of treatment-experienced children (aged 6–17 years), DELPHI, twice-daily darunavir/ritonavir-based therapy was well tolerated and 48% of the children achieved HIV-1 RNA <50 copies/mL by 48 weeks. In another study of treatment-experienced pediatric participants (aged 3 to <6 years and weight ≥10 kg to <20 kg), ARIEL, 57% of subjects had HIV-1 RNA <50 copies/mL and 81% were less than 400 copies/mL after 24 weeks of treatment. Twenty children completed the trial; 1 stopped prematurely because of vomiting. Based on data from these studies and the findings of high potency and low toxicity in adults, darunavir/ritonavir is recommended as an alternative agent for initial therapy in HIV-infected children. Some experts, however, would only recommend darunavir/ritonavir for treatment-experienced children and reserve its use for patients with resistant mutations to other PIs.
As noted above, darunavir/ritonavir is approved for once-daily use in adults and children. In addition to the DELPHI study noted above, a PK study of 24 patients, aged 14 to 23 years receiving once-daily darunavir, demonstrated darunavir exposure similar to that in adults receiving once-daily therapy—although there was a trend toward lower exposures in those aged <18 years.82 Also, in the ARIEL study, 10 treatment-experienced children were switched from twice-daily dosing to once-daily dosing after 24 weeks of therapy. PK studies were performed after 2 weeks of once-daily dosing and demonstrated darunavir mean area under the curve 24-hour equivalent to 128% of the adult AUC 24 hour.83 Based on these findings, the FDA has approved use of once-daily darunavir in children. At this time, the Panel recommends that once-daily dosing of darunavir/ritonavir as alternative initial therapy be considered only in treatment-naive adolescents aged >12 years. Additional experience with once-daily dosing of darunavir/ritonavir in children aged ≥3 years through age 12 years is awaited. Also, if darunavir resistance-associated substitutions are present (V11I, V32I, L33F, I47V, I50V, I54L, I54M, T74P, L76V, I84V, and L89V), once-daily administration should not be used. If darunavir/ritonavir is used as alternative therapy in children aged <12 years or if any of these resistance-associated substitutions are present, the Panel recommends twice-daily dosing.

**PIs for Use in Special Circumstances**

**Atazanavir without Ritonavir Boosting in Children Aged ≥13 Years (BII*)**

Although unboosted atazanavir is FDA-approved for treatment-naive adolescents aged ≥13 years who weigh >39 kg and are unable to tolerate ritonavir, data from the IMPAACT/PACTG 1020A study indicate that higher doses of unboosted atazanavir (on a mg/m² basis) are required in adolescents than in adults to achieve adequate drug concentrations56 (see Appendix A: Pediatric Antiretroviral Drug Information for detailed information on dosing used in IMPAACT/PACTG P1020A). If using unboosted atazanavir in treatment-naive patients, clinicians should consider using a dual-NRTI combination other than didanosine/emtricitabine because this combination demonstrated inferior virologic response in adults in ACTG 5175.84 Also, unboosted atazanavir should not be used in combination with tenofovir because concomitant administration results in lower atazanavir exposure. If didanosine, emtricitabine, and atazanavir are used in combination, patients should be instructed to take didanosine and atazanavir at least 2 hours apart, to take atazanavir with food, and to take didanosine on an empty stomach. The complexity of this regimen argues against its use.

**Fosamprenavir with Low-Dose Ritonavir as Alternative Protease Inhibitor (for Children Aged ≥6 Months) (AI*)**

Fosamprenavir (the prodrug of amprenavir) is available in a pediatric liquid formulation and a tablet formulation. In an adult clinical trial, fosamprenavir with low-dose ritonavir was demonstrated to be noninferior to lopinavir/ritonavir.61 In June 2007, fosamprenavir suspension was FDA-approved for use in pediatric patients aged ≥2 years. The approval was based on two open-label studies in pediatric patients aged 2 to 18 years.85,86 PK, safety and efficacy were assessed in an international study of PI-naive and PI-experienced pediatric patients, aged 4 weeks to 2 years.87,88 Overall, fosamprenavir was well tolerated except for vomiting and effective in suppressing viral load and increasing CD4 cell count (see Appendix A: Pediatric Antiretroviral Drug Information for detailed information). These data supported FDA approval for use in PI-naive children as young as 4 weeks who were born at ≥38 weeks’ gestation and had attained a postnatal age of 28 days. Young infants, however, demonstrated low drug exposure. Fosamprenavir should always be used in combination with low-dose ritonavir boosting and only for children aged ≥6 months. Once-daily dosing of fosamprenavir is not recommended for pediatric patients.

**Nelfinavir for Children Aged ≥2 Years (BI*)**

Nelfinavir in combination with 2 NRTIs is an acceptable PI choice for initial treatment of children aged ≥2 years in special circumstances. The pediatric experience with nelfinavir-based regimens in ARV-naive and ARV-experienced children is extensive, with follow-up in children receiving the regimen for as long as 7 years.89 The drug has been well tolerated; diarrhea is the primary adverse effect. However, in clinical studies the virologic potency of nelfinavir has varied greatly, with reported rates of virologic suppression ranging...
Several studies have shown a correlation between nelfinavir trough concentrations and virologic response in treatment-naive pediatric patients. In one such study, virologic response at Week 48 was observed in 29% of children with subtherapeutic nelfinavir troughs (<0.8 mg/L) versus 80% of children with therapeutic nelfinavir troughs (>0.8 mg/L). The interpatient variability in plasma concentrations is great in children, with lower levels in younger children. The optimal dose of nelfinavir in younger children, particularly in those aged <2 years, has not been well defined. These data, combined with data in adults showing inferior potency of nelfinavir compared with other PIs and efavirenz, balanced against the advantage of a PI that is not coadministered with low-dose ritonavir for boosting, make nelfinavir an agent for use in special circumstances in treatment-naive children aged ≥2 years and not recommended for treatment of children aged <2 years.

Nelfinavir is currently available only as tablets, which can be dissolved in water or other liquids to make a slurry that is then ingested by children unable to swallow whole tablets. Dissolving nelfinavir tablets in water and swallowing whole tablets resulted in comparable PK parameters in a study in adults.

**Integrase Strand Transfer Inhibitor-Based Regimens (Integrase Strand Transfer Inhibitors plus Two-Nucleoside Reverse Transcriptase Inhibitor Backbone)**

**Summary: Integrase Strand Transfer Inhibitor-Based Regimens**

**Alternative Integrase Strand Transfer Inhibitors**

Raltegravir is FDA-approved for treatment of HIV-infected children aged ≥4 weeks and weighing ≥3 kg. It is available in film-coated tablets, chewable tablets, and single packets of granules for oral suspension. Raltegravir has a favorable safety profile and lacks significant drug interactions. The Panel considers raltegravir an alternative INSTI in children aged ≥2 years who are able to take either the chewable or film-coated tablets. The tablet formulations are not interchangeable (they are not bio-equivalent), and therefore, require different dosing. Safety and efficacy data are promising, but at this time, there are little data on raltegravir use as initial therapy in HIV-infected infants and children.

Dolutegravir has recently been approved by the FDA for use in children aged ≥12 years and weighing ≥40 kg. The approval was supported by data from a study of 23 treatment-experienced but INSTI-naive children and adolescents. The drug has a very favorable safety profile and can be dosed once daily in treatment of INSTI-naive patients.

**Integrase Strand Transfer Inhibitors for Use in Special Circumstances**

Raltegravir can be considered for use in special circumstances in infants and children aged 4 weeks to 2 years. At this time, there is limited information about the use of single packets of granules for oral suspension in children aged <2 years. For this group of children, raltegravir granules may be considered as initial therapy in special circumstances.

**Selection of Dual-Nucleoside Reverse Transcriptase Inhibitor Backbone as Part of Initial Combination Therapy**

**Summary: Selection of Dual-Nucleoside Reverse Transcriptase Inhibitor Backbone Regimen**

Dual-NRTI combinations form the backbone of combination regimens for both adults and children. Currently, 7 NRTIs (zidovudine, didanosine, lamivudine, stavudine, abacavir, emtricitabine, and tenofovir) are FDA-approved for use in children aged <13 years. Dual-NRTI combinations that have been studied in children include zidovudine in combination with abacavir, didanosine, or lamivudine; abacavir in combination with lamivudine, stavudine, or didanosine; emtricitabine in combination with stavudine or
didanosine; and tenofovir in combination with lamivudine or emtricitabine. Advantages and disadvantages of different dual-NRTI backbone options are delineated in Table 9.

In the dual-NRTI regimens listed below, lamivudine and emtricitabine are interchangeable. Both lamivudine and emtricitabine are well tolerated with few adverse effects. Although there is less experience in children with emtricitabine than with lamivudine, it is similar to lamivudine and can be substituted for lamivudine as one component of a preferred dual-NRTI backbone (i.e., emtricitabine in combination with abacavir or tenofovir or zidovudine). The main advantage of emtricitabine over lamivudine is that it can be administered once daily as part of an initial regimen. Both lamivudine and emtricitabine select for the M184V resistance mutation, which is associated with high-level resistance to both drugs; a modest decrease in susceptibility to abacavir and didanosine, and improved susceptibility to zidovudine, stavudine, and tenofovir based on decreased viral fitness.

Preferred Dual-Nucleoside Reverse Transcriptase Inhibitor Backbone Regimens (in Alphabetical Order)

Abacavir in Combination with Lamivudine or Emtricitabine (for Children ≥ 3 Months) (AI)

Abacavir in combination with lamivudine has been shown to be as potent as or possibly more potent than zidovudine in combination with lamivudine in both children and adults. In 5 years of follow-up, abacavir plus lamivudine maintained significantly better viral suppression and growth in children than did zidovudine plus lamivudine and zidovudine plus abacavir. However, retrospective observational data from African children aged <16 years suggests the possibility of worse virologic outcome with abacavir/lamivudine based first-line cART when compared to the stavudine/lamivudine-based first-line cART. Multiple confounders could have contributed to these findings and further data collection and evaluation is warranted. Additionally, abacavir/lamivudine or emtricitabine has the potential for abacavir-associated life-threatening HSRs in a small proportion of patients. Abacavir hypersensitivity is more common in individuals with certain HLA genotypes, particularly HLA-B*5701 (see Appendix A: Pediatric Antiretroviral Drug Information); however, in the United States, the prevalence of HLA-B*5701 is much lower in African Americans and Hispanics (2% to 2.5%) than in whites (8%). Prevalence in Thai and Cambodian children is approximately 4%. Pretreatment screening for HLA-B*5701 before initiation of abacavir treatment resulted in a significant reduction in the rate of abacavir HSRs in HIV-infected adults (from 7.8% to 3.4%). Before initiating abacavir-based therapy in HIV-infected children, genetic screening for HLA-B*5701 should be performed and children who test positive for HLA-B*5701 should not receive abacavir.

An advantage of an abacavir regimen is the potential to switch to once-daily dosing in children with undetectable plasma RNA after approximately 24 weeks of therapy. Three small studies have now demonstrated equivalent drug exposure following a change from a twice-daily to a once-daily dosing regimen in children aged ≥3 months who had undetectable or low, stable plasma RNA after a variable period of twice-daily abacavir dosing. Two of the three demonstrated continued virologic suppression and one did not assess viral suppression. Recently, the ARROW trial reported findings from 669 HIV-infected children who had been receiving abacavir and lamivudine twice daily for 36 weeks and were randomized to either continue twice-daily dosing or change to once-daily dosing. At 48 weeks, once-daily abacavir was non-inferior to twice-daily dosing in terms of viral suppression; therefore, the Panel suggests that in clinically stable patients with undetectable plasma RNA and stable CD4 cell counts for more than 6 months, switching from twice-daily to once-daily dosing of abacavir is recommended as part of a once-daily regimen.

Tenofovir in Combination with Lamivudine or Emtricitabine (for Adolescents, Tanner Stage 4 or 5) (AI*]

Tenofovir is FDA-approved for use in children and adolescents aged ≥2 years. Because of decreases in bone mineral density (BMD) observed in adults and children receiving tenofovir, the Panel has opted to consider use of tenofovir based on Tanner stage. We have reserved our strongest recommendation in support of using
tenofovir for adolescents who are in the late stages of or who have completed puberty (Tanner stages 4 and 5). Tenofovir can be used in younger children after weighing potential risks of decreased BMD versus benefits of therapy. In comparative clinical trials in adults, tenofovir when used with lamivudine or emtricitabine as a dual-NRTI backbone was superior to zidovudine used with lamivudine and efavirenz in viral efficacy.\textsuperscript{129,130} In ACTG 5202, adults who had a screening HIV-1 RNA $\geq$100,000 copies/mL receiving tenofovir/emtricitabine as part of a cART regimen had a longer time to virologic failure and to first adverse event compared to those assigned to abacavir/lamivudine.\textsuperscript{131} However, this has not been demonstrated in other comparative trials or in a meta-analysis.\textsuperscript{132,133} Tenofovir has been studied in HIV-infected children in combination with other NRTIs and as an oral sprinkle/granule formulation.\textsuperscript{109-112} The use of tenofovir in pediatric patients aged 2 years to <18 years is approved by the FDA based on data from 2 randomized studies. In study 321, 87 treatment-experienced subjects aged 12 to <18 years were randomized to receive tenofovir or placebo plus optimized background regimen for 48 weeks. Although there was no difference in virologic response between the two groups, the safety and PKs of tenofovir in children in the study were similar to those in adults receiving tenofovir.\textsuperscript{114} In study 352, ninety-two treatment-experienced children aged 2 years to <18 years with virologic suppression on stavudine- or zidovudine-containing regimens were randomized to either replace stavudine or zidovudine with tenofovir or to continue their original regimen. After 48 weeks, 89% of subjects receiving tenofovir and 90% of subjects continuing their original regimen had HIV-1 RNA concentrations <400 copies/mL.\textsuperscript{114} Tenofovir in combination with lamivudine or emtricitabine is a preferred dual-NRTI combination for use in adolescents Tanner Stage 4 or 5 (AI\textsuperscript{*}). The fixed-dose combination of tenofovir and emtricitabine and the fixed-dose triple combination of tenofovir, emtricitabine, and efavirenz both allow for once-daily dosing, which may help improve adherence in older adolescents.

In some but not all studies, decreases in BMD have been observed in both adults and children taking tenofovir for 48 weeks.\textsuperscript{109-112,134,135} At this time, data are insufficient to recommend use of tenofovir as part of a preferred regimen for initial therapy in infected children in Tanner Stages 1 through 3, for whom the risk of bone toxicity may be greatest\textsuperscript{109,112} (see Appendix A: Pediatric Antiretroviral Drug Information for more detailed pediatric information). It is important to note that although decreases in BMD are observed, the clinical significance of these changes is not yet known. Renal toxicity has been reported in children receiving tenofovir.\textsuperscript{136-139} Given the potential for bone and renal toxicity, tenofovir may be more useful for treatment of children in whom other ARV drugs have failed than for initial therapy of treatment-naive younger children. Numerous drug-drug interactions with tenofovir and other ARV drugs, including didanosine, lopinavir/ritonavir, atazanavir, and tipranavir, complicate appropriate dosing of tenofovir.

Both emtricitabine and lamivudine, and tenofovir have antiviral activity and efficacy against hepatitis B virus (HBV). For a comprehensive review of this topic and interactions of ARV drugs with treatment for hepatitis C virus (HCV) and tuberculosis the reader should access the Pediatric Opportunistic Infections Guidelines.

**Zidovudine in Combination with Lamivudine or Emtricitabine (For Children Aged <13 Years) (AI\textsuperscript{*})**

The most extensive experience in children is with zidovudine in combination with lamivudine. Data on the safety of this combination in children are extensive and the combination is generally well tolerated.\textsuperscript{140} The major toxicities associated with zidovudine/lamivudine are bone marrow suppression, manifested as macrocytic anemia and neutropenia, and an association with lipoatrophy; minor toxicities include gastrointestinal toxicity and fatigue. In addition, the combination of zidovudine and lamivudine is acceptable in infants less than 3 months. Because zidovudine must be administered twice daily, use in adolescents (aged $\geq$13 years) is an alternative rather than a preferred agent.

**Alternative Dual-Nucleoside Reverse Transcriptase Inhibitor Regimens**

Alternative dual-NRTI combinations include zidovudine in combination with abacavir or didanosine (BII), didanosine in combination with lamivudine or emtricitabine (BI\textsuperscript{*}), zidovudine with lamivudine or emtricitabine in adolescents (aged $\geq$13 years) (AI\textsuperscript{*}), and tenofovir in combination with lamivudine or emtricitabine in children and adolescents who are Tanner Stage 3 (as opposed to Tanner Stages 4 and 5,
where this is a preferred dual-NRTI regimen) (BI*). There is considerable experience with use of these dual-NRTI regimens in children, and in a large pediatric study, the combination of zidovudine and didanosine had the lowest rate of toxicities. However, zidovudine/abacavir and zidovudine/lamivudine had lower rates of viral suppression and more toxicity leading to drug modification than did abacavir/lamivudine in a European pediatric study. The combination of didanosine and emtricitabine allows for once-daily dosing. In a study of 37 treatment-naive children aged 3 to 21 years, long-term virologic suppression was achieved with a once-daily regimen of didanosine, emtricitabine, and efavirenz; 72% of subjects maintained HIV RNA suppression to <50 copies/mL through 96 weeks of therapy. Prescribing information for didanosine recommends administration on an empty stomach. However, this is impractical for infants who must be fed frequently and it may decrease medication adherence in older children because of the complexity of the regimen. A comparison of didanosine given with or without food in children found that systemic exposure was similar but with slower and more prolonged absorption with food. To improve adherence, some practitioners recommend administration of didanosine without regard to timing of meals for young children. However, data are inadequate to allow a strong recommendation at this time, and it is preferable to administer didanosine under fasting conditions when possible.

**Dual-Nucleoside Reverse Transcriptase Inhibitor Backbone Regimens for Use in Special Circumstances**

The dual-NRTI combinations of stavudine with lamivudine or emtricitabine in children of any age are recommended for use in special circumstances. Stavudine is recommended for use only in special circumstances because the ARV is associated with a higher risk of lipoatrophy and hyperlactatemia than other NRTI drugs. Children receiving dual-NRTI combinations containing stavudine had higher rates of clinical and laboratory toxicities than children receiving zidovudine-containing combinations. However, in a prospective study, 365 treatment-naive children were randomized to stavudine, zidovudine, or abacavir as part of a cART regimen. After 96 weeks, there were no differences in overall tolerability, CD4 change, or virologic response among the groups. There was no difference in skinfold z-scores among the groups, however, 2 children randomized to stavudine underwent a drug substitution due to lipodystrophy. In children with anemia in whom there are concerns related to abacavir hypersensitivity or who are too young to receive abacavir or tenofovir, stavudine may be preferable to zidovudine for initial therapy because of its lower incidence of hematologic toxicity.

In children aged ≥2 years and those who are prepubertal or in the early stages of puberty (Tanner Stages 1 and 2), tenofovir in combination with lamivudine or emtricitabine is also recommended for use in special circumstances. As discussed above, the use of tenofovir during puberty when bone toxicity may be greatest may require caution. However, tenofovir may be a reasonable choice for initial therapy in children with demonstrated resistance to other NRTIs, coinfection with hepatitis B virus, or in those desiring a once-daily NRTI where abacavir is not an option. The Panel awaits additional safety data, especially with the recently licensed powder formulation, before providing a broader recommendation in younger children.

Both emtricitabine and lamivudine, and tenofovir have antiviral activity and efficacy against hepatitis B. For a comprehensive review of this topic, and hepatitis C virus and tuberculosis during HIV coinfection the reader should access the [Pediatric Opportunistic Infections Guidelines](#).
A cART regimen in treatment-naive children generally contains one NNRTI plus a two-NRTI backbone or one PI (generally with low-dose ritonavir boosting) plus a two-NRTI backbone. Regimens should be individualized based on advantages and disadvantages of each combination (see Table 9).

### Preferred Regimens

<table>
<thead>
<tr>
<th>Children aged ≥14 days to &lt;3 years&lt;sup&gt;a&lt;/sup&gt;</th>
<th>Two NRTIs plus LPV/r</th>

</table>

### 2-NRTI Regimens for Use in Special Circumstances

- d4T plus (3TC or FTC)
- TDF plus (3TC or FTC) (prepubertal children aged ≥2 years and adolescents, Tanner Stage 1 or 2)
a LPV/r should not be administered to neonates before a postmenstrual age (first day of the mother’s last menstrual period to birth plus the time elapsed after birth) of 42 weeks and postnatal age ≥14 days.

b EFV is licensed for use in children aged ≥3 months who weigh ≥3.5 kg but is not recommended by the Panel as initial therapy in children aged ≥3 months to 3 years. Unless adequate contraception can be ensured, EFV-based therapy is not recommended for adolescent females who are sexually active and may become pregnant.

c NVP should not be used in postpubertal girls with CD4 cell count >250/mm³, unless the benefit clearly outweighs the risk. NVP is FDA-approved for treatment of infants aged ≥15 days.

d RAL pills or chewable tablets can be used in children aged ≥2 years as an alternate INSTI. Use of granules or chewable tablets in infants and children aged 4 weeks to 2 years can be considered in special circumstances.

e DRV once daily should not be used if any one of the following resistance-associated substitutions are present (V11I, V32I, L33F, I47V, I50V, I54L, I54M, T74F, L76V, I84V, and L89V).

f FPV with low-dose RTV should only be administered to infants born at ≥38 weeks’ gestation who have attained a postnatal age of 28 days and to infants born before 38 weeks’ gestation who have reached a postmenstrual age of 42 weeks.

Key to Acronyms: 3TC = lamivudine; ABC = abacavir; ARV = antiretroviral; ATV = atazanavir; cART = combination antiretroviral therapy; d4T = stavudine; ddI = didanosine; DRV = darunavir; DTG = dolutegravir; EFV = efavirenz; FPV = fosamprenavir; FTC = emtricitabine; INSTI = integrase strand transfer inhibitor; LPV/r = fixed dose formulation lopinavir/ritonavir; NFV = nevirapine; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; RAL = raltegravir; RTV = ritonavir; TDF = tenofovir; ZDV = zidovudine

| **PIs** | FPV/r | • Oral prodrug of APV with lower pill burden  
• Pediatric formulation available, which should be given to children with food. | • Skin rash  
• More limited pediatric experience than preferred PI  
• Must be given with food to children.  
• RTV component associated with large number of drug interactions (see RTV).  
• Contains sulfamethoxazole. Potential for cross-sensitivity between FPV and other drugs in sulfonamide class is unknown.  
• Should only be administered to infants born at ≥38 weeks’ gestation and who have attained a postnatal age of 28 days. |
| **LPV/r** | | • LPV only available co-formulated with RTV in liquid and tablet formulations.  
• Tablets can be given without regard to food but may be better tolerated when taken with meal or snack. | • Poor palatability of liquid formulation (bitter taste), although palatability of combination better than RTV alone.  
• Food effect (liquid formulation should be administered with food).  
• RTV component associated with large number of drug interactions (see RTV).  
• Should not be administered to neonates before a postmenstrual age (first day of the mother’s last menstrual period to birth plus the time elapsed after birth) of 42 weeks and a postnatal age ≥14 days.  
• Must be used with caution in patients with pre-existing conduction system defects (can prolong PR and QT interval of ECG). |
| **NFV** | | • Can give with food.  
• Simplified 2-tablet (625 mg) twice-daily regimen has a reduced pill burden compared with other PI-containing regimens in older patients where the adult dose is appropriate. | • Diarrhea  
• Food effect (should be administered with food).  
• Appropriate dosage for younger children not well defined.  
• Adolescents may require higher doses than adults.  
• Less potent than boosted PI. |
| **INSTI** | Integrase Inhibitor Class Advantages:  
• Susceptibility of HIV to a new class of ARVs | Integrase Inhibitor Class Disadvantages:  
• Limited data on pediatric dosing or safety |
| DTG | • Once-daily administration  
• Can give with food. | • Limited data on pediatric dosing or safety.  
• Drug interactions with EFV, FPV/r, TPV/r, and rifampin necessitating twice daily dosing. |
| RAL | • Susceptibility of HIV to a new class of ARVs.  
• Can give with food.  
• Available in a chewable tablet and powder formulation | • Limited data on pediatric dosing or safety.  
• Potential for rare systemic allergic reaction or hepatitis |

| Dual-NRTI Backbones In Alphabetical Order | ABC plus (3TC or FTC) | • Palatable liquid formulations  
• Can give with food.  
• ABC and 3TC are co-formulated as a single pill for older/larger patients; ABC, 3TC are also co-formulated with DTG for use in adults. | • Risk of ABC HSR; perform HLA-B*5701 screening before initiation of ABC treatment. |
|           | d4T plus (3TC or FTC) | • Extensive pediatric experience  
• Palatable liquid formulations  
• Can give with food.  
• FTC is available as a palatable liquid formulation administered once daily. | • d4T associated with higher incidence of hyperlactatemia/lactic acidosis, lipoatrophy, peripheral neuropathy, hyperlipidemia. |
|           | ddl plus (3TC or FTC) | • Delayed-release capsules of ddl may allow once-daily dosing in children aged ≥ 6 years, weighing ≥ 20 kg, able to swallow pills, and who can receive adult dosing along with once-daily FTC.  
• FTC available as a palatable liquid formulation administered once daily. | • Food effect (ddl is recommended to be taken 1 hour before or 2 hours after food). Some experts give ddl without regard to food in infants or when adherence is an issue (ddl can be co-administered with FTC or 3TC).  
• Limited pediatric experience using delayed-release ddl capsules in younger children  
• Pancreatitis, lactic acidosis, neurotoxicity with ddl. |
|           | TDF plus (3TC or FTC) for adolescents, Tanner Stage 4 or 5 | • Resistance slow to develop.  
• Once-daily dosing for TDF  
• Less mitochondrial toxicity than other NRTIs  
• Can give with food.  
• TDF and FTC are co-formulated as single pill for older/larger patients.  
• Available as reduced-strength tablets and oral powder for use in younger children. | • Limited pediatric experience  
• Potential bone and renal toxicity, may be less in postpubertal children.  
• Appropriate dosing is complicated by numerous drug-drug interactions with other ARV agents including ddl, LPV/r, ATV, and TPV. |
|           | ZDV plus (3TC or FTC) | • Extensive pediatric experience  
• ZDV and 3TC are co-formulated as single pill for older/larger patients.  
• Palatable liquid formulations  
• Can give with food.  
• FTC is available as a palatable liquid formulation administered once daily. | • Bone marrow suppression with ZDV  
• Lipoatrophy with ZDV |
|           | ZDV plus ABC | • Palatable liquid formulations  
• Can give with food. | • Risk of ABC HSR; perform HLA-B*5701 screening before initiation of ABC treatment.  
• Bone marrow suppression and lipoatrophy with ZDV. |
|           | ZDV plus ddl | • Extensive pediatric experience  
• Delayed-release capsules of ddl may allow once-daily dosing of ddl in older children able to swallow pills and who can receive adult doses. | • Bone marrow suppression and lipoatrophy with ZDV.  
• Pancreatitis, neurotoxicity with ddl.  
• ddl liquid formulation is less palatable than 3TC or FTC liquid formulation.  
• Food effect (ddl is recommended to be taken 1 hour before or 2 hours after food). Some experts give ddl without regard to food in infants or when adherence is an issue. |

What Not to Start: Regimens Not Recommended for Initial Therapy of Antiretroviral-Naive Children  *(Last updated April 27, 2015; last reviewed April 27, 2015)*

Many additional antiretroviral (ARV) agents and combinations are available; some are not recommended for initial therapy, although they may be used in treatment-experienced children. This section describes ARV drugs and drug combinations that are not recommended or for which data are insufficient to recommend use for initial therapy in ARV-naive children.

**Not Recommended**

These include drugs and drug combinations that are not recommended for initial therapy in ARV-naive children because of inferior virologic response, potential serious safety concerns (including potentially overlapping toxicities), or pharmacologic antagonism. These drugs and drug combinations are listed in Table 10.

**Insufficient Data to Recommend**

Drugs and drug combinations approved for use in adults that have insufficient, limited, and/or no pharmacokinetic (PK) or safety data for children cannot be recommended as initial therapy in children. However, these drugs and drug combinations may be appropriate for consideration in management of treatment-experienced children (see Management of Children Receiving Antiretroviral Therapy). These drugs are also listed in Table 10.

**Antiretroviral Drugs and Combinations Not Recommended for Initial Therapy**

In addition to the regimens listed below, several ARVs—including unboosted atazanavir in adolescents aged <13 years, nelfinavir and tenofovir disoproxil fumarate (tenofovir) in children aged <2 years, unboosted darunavir, once-daily dosing of lopinavir/ritonavir, and full-dose ritonavir—are not recommended for use as initial therapy.

**Enfuvirtide-Based Regimens**

Enfuvirtide, a fusion inhibitor, is Food and Drug Administration (FDA)-approved for use in combination with other ARV drugs to treat children aged ≥6 years who have evidence of HIV replication despite ongoing combination antiretroviral therapy (cART) (i.e., treatment-experienced children on non-suppressive regimens). Enfuvirtide is not recommended as initial therapy because the drug must be administered subcutaneously twice daily and is associated with a high incidence of local injection site reactions (98%).

**Fosamprenavir Without Ritonavir Boosting**

Fosamprenavir without ritonavir boosting has been studied in children aged ≥2 years but is not recommended because the large volume of fosamprenavir oral suspension necessary to administer in the absence of ritonavir boosting is prohibitive. In addition, low levels of exposure may result in selection of resistance mutations that are associated with darunavir resistance.

**Indinavir-Based Regimens**

Although adequate virologic and immunologic responses have been observed with indinavir-based regimens in adults, the drug is not available in a liquid formulation and high rates of hematuria, sterile leukocyturia, and nephrolithiasis have been reported in pediatric patients using indinavir.1-4 The incidence of hematuria and nephrolithiasis with indinavir therapy may be higher in children than adults.1,4 Therefore, indinavir alone or with ritonavir boosting is not recommended as initial therapy in children.

**Regimens Containing Only Nucleoside Reverse Transcriptase Inhibitors**

In adult trials, regimens containing only nucleoside reverse transcriptase inhibitors (NRTIs) have shown less potent virologic activity when compared with more potent non-nucleoside reverse transcriptase inhibitor (NNRTI)- or protease inhibitor (PI)-based regimens. These include studies of zidovudine plus abacavir plus...
lamivudine, stavudine plus didanosine plus lamivudine, stavudine plus lamivudine plus abacavir, didanosine plus stavudine plus abacavir, tenofovir plus abacavir plus lamivudine, and tenofovir plus didanosine plus lamivudine.⁵,⁶ Data on the efficacy of triple-NRTI regimens for treatment of ARV-naive children are limited; in small observational studies, response rates of 47% to 50% have been reported.⁷ In a study of the triple-NRTI regimen abacavir, lamivudine, and zidovudine in previously treated children, the combination showed evidence of only modest viral suppression, with only 10% of 102 children maintaining a viral load of <400 copies/mL at 48 weeks of treatment.⁹ Therefore, regimens containing only NRTIs are not recommended. A possible exception to this recommendation is the treatment of young children (aged <3 years) with concomitant HIV infection and tuberculosis for whom a nevirapine-based regimen is not acceptable. For these children, where treatment choices are limited, the World Health Organization recommends the use of a triple-NRTI regimen.¹⁰

**Regimens Containing Three Drug Classes**

Data are insufficient to recommend initial regimens containing agents from three drug classes (e.g., NRTI plus NNRTI plus PI). Although studies containing three classes of drugs have demonstrated these regimens to be safe and effective in previously treated HIV-infected children and adolescents, these regimens have not been studied as initial therapy in treatment-naive children and adolescents and have the potential for inducing resistance to three drug classes, which could severely limit future treatment options.¹¹⁻¹⁵ Ongoing studies, however, are investigating three drug classes as treatment in HIV-infected neonates.

**Regimens Containing Three NRTIs and an NNRTI**

Data are currently insufficient to recommend a regimen of three NRTIs plus an NNRTI in young infants. A recent review of nine cohorts from 13 European countries suggested superior responses to this four-drug regimen when compared to boosted PI or three-drug NRTI regimens.¹⁶ There has been speculation that poor tolerance and adherence to a PI-based regimen may account for differences. The ARROW trial conducted in Uganda and Zimbabwe randomized 1,206 children (median age 6 years) to a standard NNRTI-based three-drug regimen versus a four-drug regimen (three NRTIs and an NNRTI). After a 36-week induction period, the children on the four-drug regimen were continued on a dual NRTI plus NNRTI or an all NRTI-based regimen. Although early benefits in CD4 T lymphocyte improvement and virologic control were observed in the four-drug arm, these benefits were not sustained after de-intensification to the three-NRTI arm.¹⁷ Furthermore, after a median of 3.7 years on therapy, children in the initial four-drug arm who changed to an all NRTI-based regimen had significantly poorer virologic control.¹⁸ Based on demonstrated benefits of recommended three-drug regimens and lack of additional efficacy data on the four-drug regimen, the Panel does not currently recommend this regimen.

**Saquinavir with Low-Dose Ritonavir**

A saquinavir/ritonavir-based regimen compared with a lopinavir/ritonavir-based regimen demonstrated comparable virologic and immunologic outcomes when used as initial therapy in treatment-naive adults.¹⁹ However, saquinavir is not recommended for initial therapy in children because the agent is not available in a pediatric formulation, and dosing and outcome data on saquinavir use in children are limited.

**Stavudine in Combination with Didanosine**

The dual-NRTI combination of stavudine/didanosine is not recommended for use as initial therapy because of greater toxicity when used in combination. In small pediatric studies, stavudine/didanosine demonstrated virologic efficacy and was well tolerated.²⁰⁻²² However, in studies in adults, stavudine plus didanosine-based combination regimens were associated with greater rates of neurotoxicity, pancreatitis, hyperlactatemia and lactic acidosis, and lipodystrophy than therapies based on zidovudine plus lamivudine.²³,²⁴ In addition, cases of fatal and non-fatal lactic acidosis with pancreatitis/hepatic steatosis have been reported in women receiving this combination during pregnancy.²⁵,²⁶

**Tipranavir-Based Regimens**

This agent has been studied in treatment-experienced children and adults. Tipranavir is a PI licensed for use
in children aged ≥2 years. Tipranavir-based regimens are not recommended because higher doses of ritonavir to boost tipranavir must be used and rare, but serious, cases of intracranial hemorrhage have been reported.

**Antiretroviral Drugs and Combinations with Data Insufficient to Recommend for Initial Therapy in Children**

A number of ARV drugs and drug regimens are not recommended for initial therapy in ARV-naive children or for specific age groups because of insufficient pediatric data. These include the dual-NRTI backbone combinations abacavir/didanosine, abacavir/tenofovir, and didanosine/tenofovir. In addition, several new agents appear promising for use in adults but do not have sufficient pediatric PK and safety data to recommend their use as components of an initial therapeutic regimen in children. These agents include maraviroc (CCR5 antagonist), elvitegravir (integrase strand transfer inhibitor [INSTI]), and etravirine and rilpivirine (both NNRTIs). In addition, some dosing schedules may not be recommended in certain age groups based on insufficient data. As new data become available, these agents may be considered as recommended agents or regimens. These are summarized below and also listed in Table 10.

**Darunavir with Low-Dose Ritonavir when Administered Once Daily (for Children Aged ≥3 to 12 Years)**

Data are limited on PK of once-daily darunavir/ritonavir in young children. While modeling studies identified a once-daily dosing regimen now approved by FDA, the Panel is concerned about the lack of efficacy data for individuals aged ≥3 to <12 years treated with once-daily darunavir/ritonavir. Therefore once-daily dosing for initial therapy is not recommended in this age group. For children aged ≥3 to <12 years, twice-daily darunavir boosted with ritonavir is an alternate PI regimen. For older children who have undetectable viral load on twice-daily therapy with darunavir/ritonavir, practitioners can consider changing to once-daily treatment to enhance ease of use and support adherence if no darunavir-associated resistance mutations are present.

**Dolutegravir for Children Aged <12 Years**

Dolutegravir is an INSTI that has recently been approved by FDA for use in children 12 years and older and weighing at least 40 kg. At this time there is no information about its use in children aged <12 years, but a clinical trial in treatment-experienced children aged <12 years is under way.

**Efavirenz for Children Aged ≥3 Months to 3 Years**

Efavirenz is FDA-approved for use in children as young as 3 months who weigh at least 3.5 kg. Concerns regarding variable PK of the drug in the very young have resulted in a recommendation to not use efavirenz in children younger than 3 years at this time (see Efavirenz in Appendix A: Pediatric Antiretroviral Drug Information). Based on the recommended efavirenz dosage for children younger than 3 years, the IMPAACT P1070 study estimated the variability in area under the curve (AUC) for efavirenz based on polymorphisms in cytochrome P (CYP) 2B6 516. The findings suggest that 38% of extensive metabolizers would have subtherapeutic AUCs and 67% of poor metabolizers would have excessive AUCs based on recommended dosing. Thus, should efavirenz be considered, CYP2B6 genotyping that predicts efavirenz metabolic rate should be performed, if available. Therapeutic drug monitoring can also be considered.

**Elvitegravir-Based Regimens**

Elvitegravir is an INSTI available as a tablet and as a fixed-dose combination tablet containing elvitegravir/cobicistat/emtricitabine/tenofovir. It is FDA-approved for use as cART in HIV-1-infected cART-naive adults. Elvitegravir tablets must be taken in combination with a low-dose, ritonavir-boosted PI. Neither formulation is FDA-approved for use in children aged <18 years. A small study (14 participants) of the fixed-dose combination tablet containing elvitegravir/cobicistat/emtricitabine/tenofovir in treatment-naive children and adolescents, aged 12 to 17 years, has reported PK, tolerability, and virologic efficacy at 24 weeks. The therapy was well tolerated and all participants taking the cART at 24 weeks had viral loads less than 400 copies/mL; 11 had viral loads less than 50 copies/mL. Steady state exposure was similar to that observed in...
adults, as were small increases in serum creatinine without evidence of nephrotoxicity. These data suggest that elvitegravir/cobicistat/emtricitabine/tenofovir is efficacious in children and adolescents aged 12 to 18 years, but evidence is insufficient for this regimen to be recommended as initial therapy for treatment-naive children and adolescents in this age group.

**Etravirine-Based Regimens**

Etravirine is an NNRTI that has been studied in treatment-experienced children 6 years and older.\(^{28,29}\) It is associated with multiple interactions with other ARVs, including tipranavir/ritonavir, fosamprenavir/ritonavir, atazanavir/ritonavir, and unboosted PIs, and must be administered twice daily. Studies in treatment-experienced younger children are under way. It is unlikely that etravirine will be studied in treatment-naive children.

**Rilpivirine-Based Regimens**

Rilpivirine is currently available both as a single-agent formulation and a once-daily, fixed-dose combination tablet containing emtricitabine and tenofovir. A recent study of rilpivirine, 25 mg daily in combination with two NRTIs in treatment-naive adolescents aged 12 to 18 years, demonstrated that the regimen was well-tolerated over 24 weeks. Among adolescents with baseline viral loads ≤100,000 copies/mL, 86% had a virologic response.\(^{30}\) In adult studies, reduced viral suppression was observed in patients with initial HIV RNA >100,000 copies/mL; similar reduced response was also observed in the pediatric study. In adults, rilpivirine is recommended only if HIV RNA is ≤100,000 copies/mL; it is not recommended as initial therapy for treatment-naive children and adolescents, and if used in older children and adolescents (aged >12 years) it should only be used if HIV RNA is <100,000 copies/mL.

**Maraviroc-Based Regimens**

Maraviroc is an entry inhibitor that has been used infrequently in children. A dose-finding study in treatment-experienced children aged 2 to 18 years is enrolling patients in four age cohorts using both liquid and tablet formulations. Initial dose is based on body surface area and scaled from recommended adult dosage. Dose adjustments were required in patients not receiving a potent CYP450 3A4 inhibitor or inducer.\(^{31}\) The drug has multiple drug interactions and must be administered twice daily. In addition, tropism assays must be performed prior to use to ensure the presence of only CCR5-tropic virus.

**Antiretroviral Drug Regimens that Should Never Be Recommended**

Several ARV drugs and drug regimens should never be recommended for use in therapy of children or adults. These are summarized in Table 11. Clinicians should be aware of the components of fixed-drug combinations so that patients do not inadvertently receive a double dose of a drug contained in such a combination.

Specific Issues in Antiretroviral Therapy for Neonates (Last updated March 5, 2015; last reviewed March 5, 2015)

Existing pharmacokinetic (PK) and safety data are insufficient for the recommendation of a complete combination antiretroviral therapy (cART) regimen to treat preterm infants and term infants younger than 15 days (until 42 weeks postmenstrual age).

Until recently, neonatal antiretroviral (ARV) regimens were designed for prophylaxis of perinatal HIV transmission and to be as simple as possible for practical use in resource-poor countries. There was little reason to develop ARV regimens for treatment of neonates, as the long turnaround times to receive HIV nucleic acid testing (NAT) results meant that neonatal infections were generally not diagnosed in the first weeks of life. However, because HIV NAT test results now often are available within a few days, HIV-infected infants are being diagnosed as early as the first days of life. In addition, the recent case of prolonged remission of HIV infection in an infant from Mississippi has led to discussions about strategies to achieve prolonged virologic suppression of *in utero* HIV infection with early intensive ARV treatment and subsequent treatment interruption. This interest must be tempered by:

- Lack of evidence that very early treatment (before age 2 weeks) will produce a prolonged remission or lead to better outcomes in infected infants
- The very limited dosing and safety data for ARV drugs in the newborn period
- The potential for toxicity from ARV agents.

Sufficient data exist to provide dosing recommendations appropriate for the treatment of HIV infection in neonates using the following medications:

- From birth in term and preterm infants: *zidovudine*
- From birth in term neonates: *lamivudine, emtricitabine*, and *stavudine*
- From age 2 weeks in term neonates: *didanosine, nevirapine*, and *lopinavir/ritonavir*

For all other ARV drugs, PK and safety data are insufficient to allow recommendations for safe doses appropriate for use in HIV infected neonates.

Data are insufficient on which to base a firm recommendation for treatment doses of nevirapine in newborn infants. Nevirapine PK data in neonates come from studies designed to identify doses appropriate for *prophylaxis*, not treatment, of HIV infection. The target plasma trough concentration in nevirapine perinatal prophylaxis studies was 0.1 microgram/mL, which would be inadequate for sustained therapeutic effect in an HIV infected individual. No neonatal PK data exist for regimens designed to achieve the suggested therapeutic plasma target concentration of 3.0 microgram/mL. A population analysis of nevirapine PK data collected during the first year of life combining both prevention and treatment studies demonstrated that nevirapine clearance is low immediately after birth and increases dramatically over the first months of life. Simulations derived from this model suggest that 6 mg/kg of nevirapine administered twice daily to full-term infants in the first 4 weeks of life will maintain trough concentrations above 3.0 microgram/mL. This dose will be studied in the IMPAACT P1115 clinical trial.

The experience with lopinavir/ritonavir in neonates highlights the risk of using ARVs in neonates without neonatal PK and safety data. Life-threatening cardiovascular, renal, and central nervous system toxicity have been reported in 10 infants (8 preterm, 2 term) receiving lopinavir/ritonavir oral solution during the first weeks of life. These toxicities included bradycardia, complete atrioventricular block, heart failure, renal failure, respiratory failure, metabolic acidosis, hypotonia and central nervous system depression, and one infant died of cardiogenic shock. Lopinavir/ritonavir oral solution contains ethanol (42.4% w/v) and propylene glycol (15.3% w/v), and the contributions of lopinavir, ritonavir, ethanol, and propylene glycol exposure to the observed toxicities are not clear. While a small study of trough lopinavir plasma concentrations in premature infants and a larger-population PK study in infants including neonates provide
Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

some preliminary PK data, they are insufficient to currently allow a recommendation for safe and effective ritonavir-boosted lopinavir dosing immediately following birth.7,8 The Food and Drug Administration recommends against the use of lopinavir-ritonavir oral solution in premature infants until 14 days after their due date, or in full-term infants younger than 42 weeks postmenstrual age.6

While there is considerable interest in the use of integrase inhibitors in neonates, data are lacking to formulate a safe dosing recommendation in neonates. Neonatal washout elimination of raltegravir that crossed the placenta after maternal administration is highly variable, with a half-life ranging from 9.3 to 184 hours over the first days of life.9 As raltegravir competes with bilirubin for protein binding and for elimination through glucuronidation, increased plasma raltegravir concentrations may lead to increased plasma concentrations of free unconjugated bilirubin, posing the risk of bilirubin encephalopathy and kernicterus, particularly in preterm infants who have decreased bilirubin elimination, decreased albumin binding capacity and an immature blood-brain barrier.10 Use of the recently approved oral granule raltegravir formulation in neonates should be avoided until adequate neonatal PK and safety data are available.

Current recommendations for ARV prophylaxis for prevention of perinatal HIV transmission in high-risk infants in the United States (e.g., limited prenatal maternal ARV therapy, high maternal viral load) are for use of zidovudine and nevirapine dosed according to the NICHD-HPTN 040 regimen.11,12 The nevirapine regimen used in NICHD-HPTN 040 was designed to maintain nevirapine concentrations above 0.1 microgram /mL, the drug concentration target used in studies of prevention of HIV transmission, not the 3.0 microgram /mL target used in treatment of HIV-infected individuals.13 In this study, both 2- and 3-drug combination regimens were superior to zidovudine prophylaxis alone to prevent intrapartum transmission; however, there was no incremental benefit of the 3-drug regimen (lamivudine and nelfinavir for 2 weeks plus zidovudine for 6 weeks) compared to the 2-drug regimen (3 doses of nevirapine in the first week of life plus 6 weeks of zidovudine) in prevention of perinatal transmission. The three-drug regimen had significantly more hematologic toxicity and the powder nelfinavir formulation is no longer commercially available.

Despite these data, combination treatment of infants at high risk of HIV infection before diagnostic test results indicating infection are available has been increasing. The European Pregnancy and Paediatric HIV Cohort Collaboration (EPPICC) has pooled data from 5,285 mother-infant pairs considered at high risk of perinatal transmission (no antepartum maternal treatment or detectable maternal viremia despite treatment) included in eight European cohorts and evaluated the use of combination prophylaxis. Among the 1,105 infants receiving combination prophylaxis, 13.5% received zidovudine plus lamivudine, 22.7% received zidovudine plus single-dose nevirapine, 55.8% received zidovudine plus single-dose nevirapine plus lamivudine, and 4.4% received a regimen including a protease inhibitor. In these observational cohorts, there was no difference in infant infection rates between one drug and combination prophylactic regimens.14 As discussed above, the data necessary for safe and appropriate neonatal dosing of all components of a three-drug ARV regimen for treatment of HIV infection are not currently available.

The risks associated with use of a three-drug ARV regimen in neonates as well as the potential benefits, including the possibility of prolonged remission in infected neonates, require further study before a general recommendation can be made. The Panel recommends that neonatal care providers, who are considering a 3-drug ARV treatment regimen of term infants younger than 2 weeks or premature infants, contact a pediatric HIV expert for guidance and individual case assessment of the risk/benefit ratio of treatment and for the latest information on neonatal drug doses. Providers may contact a local pediatric HIV expert or the National Perinatal HIV Hotline (1-888-448-8765), which provides free clinical consultation on perinatal HIV care.

Specific Issues in Antiretroviral Therapy for HIV-Infected Adolescents  
(Last updated March 5, 2015; last reviewed March 5, 2015)

**Panel's Recommendations**
- Combination antiretroviral therapy regimens must be individually tailored to the adolescent (AIII).
- Reproductive options including preconception care, contraception methods, and safer sex techniques for prevention of secondary HIV transmission to sexual partners should be discussed regularly (AI).
- Adolescents who are considering a planned pregnancy should be receiving a maximally suppressive combination antiretroviral therapy regimen (AII).
- Providers should be aware of potential interactions between combination antiretroviral therapy and hormonal contraceptives that could lower contraceptive efficacy (AII*).
- Pediatric and adolescent care providers should prepare adolescents for the transition into adult care settings (AIII).

**Rating of Recommendations:** A = Strong; B = Moderate; C = Optional

**Rating of Evidence:** I = One or more randomized trials in children\(^{*}\) with clinical outcomes and/or validated endpoints; I\(^{*}\) = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children\(^{†}\) from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children\(^{†}\) with long-term outcomes; II\(^{*}\) = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children\(^{†}\) from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

\(^{†}\) Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

**Background**
Most children who acquired HIV infection through perinatal transmission in the United States are adolescents or young adults. They generally have had a long clinical course and extensive history of treatment with combination antiretroviral therapy (cART).\(^{1}\) Adolescents with non-perinatally acquired HIV infection generally follow a clinical course similar to that in adults; early intervention with cART should be considered for them.\(^{2}\)

**Dosing of Antiretroviral Therapy for HIV-Infected Adolescents**
Puberty is a time of somatic growth and sexual maturation, with females developing more body fat and males more muscle mass. These physiologic changes may affect drug pharmacokinetics (PK), which is especially important for drugs with a narrow therapeutic index that are used in combination with protein-bound medicines or hepatic enzyme inducers or inhibitors.\(^{3}\)

In addition, many antiretroviral (ARV) drugs (e.g., abacavir, emtricitabine, lamivudine, tenofovir disoproxil fumarate [tenofovir], and some protease inhibitors [PIs]) are administered to children at higher weight- or surface area-based doses than would be predicted by direct extrapolation of adult doses. This is based upon reported PK data indicating more rapid drug clearance in children. Data suggesting optimal doses for every ARV drug in adolescents are not available although Appendix A: Pediatric Antiretroviral Drug Information includes a discussion of data relevant to adolescents for individual drugs and notes the age listed on the drug label for adult dosing.

**Adolescent Contraception, Pregnancy, and Antiretroviral Therapy**
HIV-infected adolescents may be sexually active and usually initiate activity during or after puberty. Reproductive health options including preconception care, contraception methods, and safer sex techniques for prevention of secondary HIV transmission should be discussed with them regularly (see U.S. Medical Eligibility Criteria for Contraceptive Use).\(^{4}\) For additional information please see the Perinatal Guidelines.
The possibility of planned and unplanned pregnancy should also be considered when selecting a cART regimen for an adolescent female. The most vulnerable period in fetal organogenesis is the first trimester, often before pregnancy is recognized. Concerns about specific ARV drugs and birth defects should be promptly addressed to preclude any misinterpretation or lack of adherence by HIV-infected pregnant adolescents (for additional information please see the Perinatal Guidelines). Currently efavirenz is the only approved ARV drug that carries Food and Drug Administration Pregnancy Class D labeling, based on neural tube defects in primates. However, a recent updated meta-analysis found no increased risk of teratogenicity associated with first-trimester efavirenz exposure. This review contributed to the evidence base for the revised 2013 World Health Organization (WHO) guidelines on ARV therapy; WHO recommends including efavirenz as part of first-line therapy in adults regardless of gender, and indicates that it can be used throughout pregnancy, including during the first trimester. However, because of the low incidence of central nervous system anomalies in the overall population and relatively small number of exposures in the current literature, continued surveillance of birth outcomes is warranted. Although increasing data on the use of efavirenz in pregnancy are reassuring, many experts remain reluctant to consider use of efavirenz in adolescent females who are trying to conceive or who are not using effective birth control. Readers should consult the Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States for guidance in selection of ARV drugs during pregnancy.

Contraceptive-Antiretroviral Drug Interactions

Several PI and non-nucleoside reverse transcriptase inhibitor drugs alter metabolism of oral contraceptives, resulting in possible decreases in ethinyl estradiol or increases in estradiol or norethindrone levels (see the Adult and Adolescent Antiretroviral Guidelines and http://www.hiv-druginteractions.org). These changes may decrease the effectiveness of the oral contraceptives or potentially increase the risk of estrogen- or progestin-related adverse effects. Some newer agents, such as integrase inhibitors (specifically raltegravir), appear to have no interaction with estrogen-based contraceptives. Providers should be aware of these drug interactions and consider alternative or additional contraceptive methods for patients receiving cART. For more information about potential interactions between ARVs and hormonal contraceptives please see Table 3 in the Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States located at http://aidsinfo.nih.gov/guidelines/html/3/perinatal-guidelines/152/overview.

Whether interactions with cART would compromise the contraceptive effectiveness of progestin-only injectable contraceptives (such as depot medroxyprogesterone acetate [DMPA]) is unknown because these methods produce higher blood hormone levels than other progestogen-only oral contraceptives and combined oral contraceptives. In one study, the efficacy of DMPA was not altered in women receiving concomitant nelfinavir-, efavirenz-, or nevirapine-based treatment, with no evidence of ovulation during concomitant administration for 3 months, no additional adverse effects, and no clinically significant changes in ARV drug levels. At this time, concerns about loss of bone mineral density (BMD) with long-term use of DMPA with or without cART (specifically tenofovir) should not preclude use of DMPA as an effective contraceptive, unless there is clinical evidence of bone fragility. However, more active monitoring of BMD in young women on DMPA may need to be considered. Minimal information exists about drug interactions with use of newer methods of hormonal contraception (e.g., the patch and vaginal ring). HIV-infected women can use all available contraceptive methods, including the transdermal patch and vaginal ring. Adolescents who want to become pregnant should be referred for preconception counseling and care, including discussion of special considerations for use of cART during pregnancy (see the Perinatal Guidelines).
and selection of regimens may be different for pregnant women than for nonpregnant women. Details regarding choice of cART regimen in pregnant HIV-infected women, including adolescents, are provided in the Perinatal Guidelines. Although information is limited about the pregnancies of adolescents who were HIV-infected perinatally, perinatal HIV transmission outcomes in this population appear similar to those in adult cohorts; however, there may be differences in pregnancy-related morbidities. Kenny et al reported pregnancy outcomes from the United Kingdom and Ireland in a group of 30 adolescents who were perinatally HIV-infected or who acquired HIV infection at a young age. Few of these pregnancies were planned and in many cases, the partner was unaware of the mother’s HIV status. Rates of elective termination, miscarriage, and prematurity were high. The rate of prematurity was twice that in the general adolescent population of Europe. Many of the women had an AIDS diagnosis before pregnancy, but only one infant was HIV-infected. Although the rate of perinatal transmission is reassuring, this study highlights some of the major challenges in caring for pregnant, perinatally HIV-infected youth.

Comparisons of pregnancy incidence and outcomes between perinatally infected and non-perinatally infected youth are few and may offer special insight into the effects of prolonged HIV infection on pregnancy-related sequelae. Agwu et al retrospectively evaluated pregnancies at four clinics. Non-perinatally infected youth were more likely to have one or more pregnancies despite similar age at first pregnancy between groups. They also appeared to have more premature births and spontaneous abortions, but that is tempered by the fact that the perinatally infected youth were more likely to have an elective termination. The perinatal transmission rate for the entire cohort was 1.5%. Similar results were found in several other studies. However, in a single-center review of perinatal versus non-perinatal birth outcomes, infants born to women who were perinatally infected with HIV were more likely to be small for gestational age. Recently Badell and colleagues noted that 20 perinatally infected pregnant women were significantly more likely to be younger, have a detectable viral load, and have HIV-genotypic resistance compared to 80 non-perinatally infected pregnant women. The median gestational age at delivery and rates of obstetrical and neonatal complications were similar between the groups. There was one case of perinatal transmission in an infant born to a perinatally infected mother versus two transmission events in offspring of the mothers who were not perinatally infected.

### Transition of Adolescents into Adult HIV Care Settings

Facilitating a smooth transition of adolescents with chronic health conditions from their pediatric/adolescent medical home to adult care can be difficult and is especially challenging for those who are HIV-infected. Transition is described as “a multifaceted, active process that attends to the medical, psychosocial, and educational or vocational needs of adolescents as they move from the child-focused to the adult-focused healthcare system.” Care models for children and adolescents with perinatally acquired HIV tend to be family-centered, consisting of a multidisciplinary team that often includes pediatric or adolescent physicians, nurses, social workers, and mental health professionals. These providers generally have long-standing relationships with patients and their families, and care is rendered in discreet, more intimate settings. Although expert care is also provided under the adult HIV care medical model, an adolescent may be unfamiliar with the more individual-centered, busier clinics typical of adult medical providers and uncomfortable with providers with whom they, in many cases, do not have a long-standing relationship. Providing an adolescent and an adult medical care provider with support and guidance regarding expectations for each partner in the patient-provider relationship may be helpful. In this situation, it may also be helpful for a pediatric and an adult provider to share joint care of a patient for a period of time. Providers should also have a candid discussion with a transitioning adolescent to understand what qualities the adolescent considers most important in an adult care setting (e.g., confidentiality, small clinic size, after-school appointments). Pediatric and adolescent providers should have a formal plan in place to transition adolescents to adult care. Some general guidelines about transitional plans and who might benefit most from them are available.

Outcomes are variable in young adult patients transitioned to adult care. Definitions of “successful transition” have ranged from the ability to maintain a certain level of follow-up in the new clinic, to laboratory measures of stability, to comparisons of younger and older adult patients. Factors that should be taken into...
consideration during transition include social determinants such as developmental status, behavioral/mental health issues, housing, family support, employment, recent discharge from foster care, peer pressure, illicit drug use, and incarceration. Psychiatric comorbidities and their effective management predict adherence to medical care and therapy. Currently there is no definitive model of transition to adult HIV care and only limited reports about outcomes following transition. One such article from the United Kingdom suggests a higher mortality risk after transition.

Adherence to Antiretroviral Therapy in HIV-Infected Children and Adolescents  (Last updated March 5, 2015; last reviewed March 5, 2015)

Panel’s Recommendations

- Strategies to maximize adherence should be discussed before initiation of combination antiretroviral therapy and again before changing regimens (AII).
- Adherence to therapy must be assessed and promoted at each visit, along with continued exploration of strategies to maintain and/or improve adherence (AII).
- At least one method of measuring adherence to combination antiretroviral therapy should be used in addition to monitoring viral load (AII).
- When feasible, a once-daily antiretroviral regimen should be considered (BI†).
- To improve and support adherence, providers should maintain a nonjudgmental attitude, establish trust with patients/caregivers, and identify mutually acceptable goals for care (AII†).

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children† with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children† from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children† with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children† from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

†Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

Background

Adherence to combination antiretroviral therapy (cART) is a principal determinant of virologic suppression.1-3 Prospective adult and pediatric studies have established a direct correlation between risk of virologic failure and the proportion of missed doses of antiretroviral (ARV) drugs.4 Based on early work in HIV-infected adults treated with unboosted protease inhibitor-based regimens, ≥95% adherence has been the threshold associated with complete viral suppression. More recent studies from adult populations suggest that the relationship between ARV adherence and viral suppression may vary with individual drug, drug class, and pattern of adherence.5 Viral suppression may be achieved with lower levels of adherence to boosted PI and non-nucleoside reverse transcriptase inhibitor regimens.5,6 In patients who achieve virologic suppression, the degree of adherence needed to prevent viral rebound appears to decrease over time.7 Different patterns of inadequate adherence (e.g., intermittent missed doses, treatment interruptions) may have a differential impact on regimen efficacy, depending on the drug combination.8,9

Poor adherence will result in sub-therapeutic plasma ARV drug concentrations, facilitating development of drug resistance to one or more drugs in a given regimen, and possibly cross-resistance to other drugs in the same class. Multiple factors (including regimen potency, pharmacokinetics, drug interactions, viral fitness, and the genetic barrier to ARV resistance) influence the adherence-resistance relationship.10 In addition to compromising the efficacy of the current regimen, suboptimal adherence has implications for limiting future effective drug regimens in patients who develop multidrug-resistant HIV and for increasing the risk of secondary transmission.

Poor adherence to ARVs is commonly encountered in the treatment of HIV-infected children and adolescents. Multiple studies have reported that fewer than 50% of children and/or caretakers reported full adherence to prescribed regimens. Rates of adherence varied with method of ascertainment (e.g., parent/child report, pharmacy records), ARV regimens, and study characteristics.2,3,11,12 A variety of factors—including medication formulation, frequency of dosing, child’s age, and psychosocial and behavioral characteristics of
children and parents—have been associated with adherence; however, no consistent predictors of either good or poor adherence in children have been consistently identified.13-15 Furthermore, several studies have demonstrated that adherence is not static and can vary with time on treatment.16 These findings illustrate the difficulty of maintaining high levels of adherence and underscore the need to work in partnership with families to ensure that adherence education, support, and assessment are integral components of care.

**Specific Adherence Issues in Children**

Adherence is a complex health behavior that is influenced by the regimen, patient and family factors, and characteristics of health care providers.14 The limited availability of palatable formulations for young children is especially problematic.4 Furthermore, infants and children are dependent on others for administration of medication; thus, assessment of the capacity for adherence to a complex, multidrug regimen requires evaluation of the caregivers and their environments, as well as the ability and willingness of a child to take the drug. Barriers faced by adult caregivers that can contribute to non-adherence in children include forgetting doses, changes in routine, being too busy, and child refusal.17,18 Some caregivers may place too much responsibility for managing medications on older children before they are developmentally able to undertake such tasks,19 whereas others themselves face health and adherence challenges related to HIV infection, substance use, or other medical conditions. Other barriers to adherence include caregivers’ unwillingness to disclose HIV infection status to the child and/or others, reluctance of caregivers to fill prescriptions locally, hiding or relabeling of medications to maintain secrecy within the household, avoidance of social support, and a tendency for doses to be missed if the parent is unavailable. Adherence may also be jeopardized by social issues within a family (e.g., substance abuse, unstable housing, and involvement with the criminal justice system).

**Specific Adherence Issues in Adolescents**

HIV-infected adolescents also face specific adherence challenges. Several studies have identified both pill burden and lifestyle issues (i.e., not having medications on hand when away from home, change in schedule) as significant barriers to effective adherence.20 Denial and fear of their HIV infection are common in adolescents, especially youth who have been recently diagnosed; this may lead to refusal to initiate or continue cART. Distrust of health care workers, misinformation about HIV, and lack of knowledge about the availability and effectiveness of ARV treatments can also be barriers to linking adolescents to care, retaining them in care, and maintaining them on successful cART.

Perinatally infected youth are familiar with the challenges of taking complex drug regimens and with the routine of chronic medical care; nevertheless, they often have long histories of inadequate adherence. Regimen fatigue also has been identified as a barrier to adherence in adolescents.21 HIV-infected adolescents often have low self-esteem, unstructured and chaotic lifestyles, concomitant mental illnesses, and cope poorly with their illness. Depression, alcohol or substance abuse, poor school attendance, psychiatric disorders and advanced HIV disease have been associated with non-adherence.22 A review of published papers on adherence among HIV-infected youth suggests that depression and anxiety are consistently associated with poorer adherence.22 Adherence to complex regimens is particularly challenging at a time of life when adolescents do not want to be different from their peers. Further difficulties include adolescents who live with parents or partners to whom they have not yet disclosed their HIV status and youth who are homeless and have no place to store medicine. When recommending treatment regimens for adolescents, clinicians must balance the goal of prescribing a maximally potent ARV regimen with a realistic assessment of existing and potential support systems to facilitate adherence.

**Adherence Assessment and Monitoring**

The process of adherence preparation and assessment should begin before therapy is initiated or changed. A routine adherence assessment should be incorporated into every clinic visit. A comprehensive assessment should be instituted for all children in whom cART initiation or change is considered. Evaluations should
include nursing, social, and behavioral assessments of factors that may influence adherence by children and their families and can be used to identify individual needs for intervention. Specific, open-ended questions should be used to elicit information about past experience as well as concerns and expectations about treatment. When assessing readiness and preparing to begin treatment, it is important to obtain a patient’s explicit agreement with the treatment plan, including strategies to support adherence. It is also important to alert patients to minor adverse effects of ARVs, such as nausea, headaches, and abdominal discomfort that may recede over time or respond to change in diet or timing of medication administration.

Adherence is difficult to assess accurately; different methods of assessment have yielded different results and each approach has limitations.12,23,24 Patients, caregivers, and health care providers often overestimate adherence although infected youth and caregivers report similar rates of adherence.25 Use of multiple methods to assess adherence is recommended.24,26 Viral load monitoring is useful in identifying patients who require enhanced adherence support.27 The viral load response to a new regimen is often the most accurate indication of adherence if the virus is susceptible to the regimen and the medication doses are appropriate. Other measures include quantitative self report of missed doses by caregivers and children or adolescents (i.e., focusing on missed doses during a recent 3-day or 1-week period), descriptions of the medication regimens, and reports of barriers to administration of medications. Caregivers may report number of doses taken more accurately than doses missed.28 Targeted questions about stress, pill burden, and daily routine are recommended. Pharmacy refill checks and pill counts can identify adherence problems not evident from self-reports.29 Electronic monitoring devices (e.g., Medication Event Monitoring System [MEMS] caps) which are equipped with a computer chip that records each opening of a medication bottle are primarily used in research studies, but have been shown to be useful tools to measure adherence in some settings. Mobile phone technologies (e.g., interactive voice response, SMS text messaging) are being evaluated to quantify missed doses and provide real-time feedback on adherence to caregivers, but studies in the pediatric population are in the pilot phase.30,31 Home visits can play an important role in assessing adherence. In some cases, suspected non-adherence is confirmed only when dramatic clinical responses to cART occur during hospitalizations or in other supervised settings. Preliminary studies suggest that monitoring plasma ARV concentrations or therapeutic drug monitoring may be useful measures in situations where non-adherence is suspected. Drug concentrations in hair are currently being studied as an alternative method to measure adherence.32,33

Adherence can change over time. An adolescent who was able to strictly adhere to treatment upon initiation of a regimen may not be able to maintain complete adherence over time. A nonjudgmental attitude and trusting relationship foster open communication and facilitate assessment. To obtain information on adherence in older children, it is often helpful to ask both HIV-infected children and their caregivers about missed doses and problems. Their reports may differ significantly; therefore, clinical judgment is required to best interpret adherence information obtained from the multiple sources.34

** Strategies to Improve and Support Adherence **

Intensive follow-up is required, particularly during the first few months after therapy is initiated. This is particularly important if treatment must be started urgently. If there are particular concerns about adherence, patients should be seen and/or contacted by phone (voice mail and text messaging) or email frequently—as often as weekly during the first month of treatment—to assess adherence and determine the need for strategies to improve and support adherence.

Strategies include the development of patient-focused treatment plans to accommodate specific patient needs, integration of medication administration into the daily routines of life (e.g., associating medication administration with daily activities such as brushing teeth), and use of social and community support services. Multifaceted approaches that include regimen-related strategies; educational, behavioral, and supportive strategies focused on children and families; and strategies that focus on health care providers—rather than one specific intervention—may be most effective.19,35,36 Programs designed for administration of directly observed combination therapy to adults, in either the clinic or at home, have demonstrated successful results in both the United States and in international, resource-poor settings.37,38 Modified directly observed
therapy (m-DOT), where one dose is administered in a supervised setting and the remaining doses are self-administered, appears to be both feasible and acceptable.^{35,39} However, a recent meta-analysis of 10 randomized clinical trials evaluating DOT to promote adherence in adults found that it was no more effective than self-administered treatment.^{40} In another meta-analysis of DOT studies, DOT was found to have a demonstrated effect on virologic, immunologic, and adherence outcomes, but efficacy of the strategy was not supported when the analysis was restricted to randomized controlled trials.^{41} Table 12 summarizes some of the strategies that can be used to support and improve adherence to ARV medications. The Centers for Disease Control and Prevention offers a web-based toolkit (consisting of four evidence-based HIV medication adherence strategies) to HIV care providers.^{42}

### Regimen-Related Strategies

ARV regimens for children often require the administration of large numbers of pills or unpalatable liquids, each with potential adverse effects and drug interactions, in multiple daily doses. To the extent possible, regimens should be simplified with respect to the number of pills or volume of liquid prescribed, as well as frequency of therapy, and chosen to minimize drug interactions and adverse effects.^{43} When non-adherence occurs, addressing medication-related issues (e.g., adverse effects) may result in improvement. If a regimen is overly complex, it can be simplified. For example, when the burden of pills is great, one or more drugs can be changed to a fixed-drug combination resulting in a regimen with fewer pills. A once-daily regimen should be considered, when feasible. Several studies in adults have demonstrated better adherence with once-daily versus twice-daily ARV regimens.^{44-46} In a meta-analysis of randomized, controlled trials in adults, a lower pill burden was associated with better adherence and viral suppression. Adherence was modestly better with once-daily regimens than with twice-daily regimens; however, rates of viral suppression did not differ.^{47} Once-daily dosing may be less forgiving of poor adherence for some medications but outcomes are likely to vary by specific drug regimen. When non-adherence is related to poor palatability of a liquid formulation or crushed pills and simultaneous administration of food is not contraindicated, the offending taste can sometimes be masked with a small amount of flavoring syrup or food (see Appendix A: Pediatric Antiretroviral Drug Information) in order to overcome medication aversion.^{48} Unfortunately, the taste of lopinavir/ritonavir cannot be masked with flavoring syrup. A small study of children aged 4 to 21 years found that training children to swallow pills has been associated with improved adherence at 6 months post-training.^{49}

### Patient/Family-Related Strategies

The primary approach taken by the clinical team to promote medication adherence in children is patient and caregiver education. Educating families about adherence should begin before ARV medications are initiated or changed and should include a discussion of the goals of therapy, the reasons for making adherence a priority, and the specific plans for supporting and maintaining a child’s medication adherence. Caregiver adherence education strategies should include the provision of both information and adherence tools, such as written and visual materials; a daily schedule illustrating times and doses of medications; and demonstration of the use of syringes, medication cups, and pillboxes.

A number of behavioral tools can be used to integrate taking medications into an HIV-infected child’s daily routine. The use of behavior modification techniques, especially the application of positive reinforcements and the use of small incentives (including financial incentives) for taking medications, can be effective tools to promote adherence.^{50} Availability of mental health services and the treatment of mental health disorders (such as depression) may facilitate adherence to complex ARV regimens.^{51} A gastrostomy tube should be considered for non-adherent children who are at risk of disease progression and who have severe and persistent aversion to taking medications.^{52} If adequate resources are available, home-nursing interventions may also be beneficial. Directly observed dosing of ARV medications has been implemented in adults, adolescents, and children, using home nursing services as well as daily medication administration in the clinic setting.

Other strategies to support adherence that have been employed in the clinical setting include setting patients’ cell phone alarms to go off at medication times; using beepers or pagers as an alarm; sending SMS text-message reminders; conducting motivational interviews; providing pill boxes and other adherence support.
tools, particularly for patients with complex regimens; and delivering medications to the home. Randomized clinical trials in adults have demonstrated that text-messaging is associated with improved adherence.\textsuperscript{53-56} In a pilot study evaluating peer support and pager messaging in an adult population, peer support was associated with greater self-reported adherence post-intervention; however, the effect was not sustained at follow-up. Although pager messaging was not associated with reported adherence, improved biologic outcomes were measured.\textsuperscript{57} Motivational interviews, including computer-based interventions, are currently being evaluated.\textsuperscript{50,58} A study evaluating the efficacy of a 4-session, individual, clinic-based, motivational, interviewing intervention targeting multiple risk behaviors in HIV-infected youth demonstrated an association with lower viral load at 6 months in youth taking cART. However, reduction in viral load was not maintained at 9 months.\textsuperscript{59} In adults, an intervention that taught managed problem solving resulted in improved adherence and viral suppression during 1 year of follow-up.\textsuperscript{60}

**Health Care Provider-Related Strategies**

Providers have the ability to improve adherence through their relationships with patients’ families. This process begins early in a provider’s relationship with a family, when the clinician obtains explicit agreement about the medication and treatment plan and any further strategies to support adherence. Fostering a trusting relationship and engaging in open communication are particularly important.\textsuperscript{61} Provider characteristics that have been associated with improved patient adherence in adults include consistency, giving information, asking questions, technical expertise, and commitment to follow-up. Creating an environment in the health care setting that is child-centered and includes caregivers in adherence support also has been shown to improve treatment outcomes.\textsuperscript{62}

### Management of Medication Toxicity or Intolerance

**Panel’s Recommendations**

- In children who have severe or life-threatening toxicity, all antiretroviral drugs should be stopped immediately (AIII). Once symptoms of toxicity have resolved, antiretroviral therapy should be resumed with substitution of a different antiretroviral drug or drugs for the offending agent(s) (AII*).

- When modifying therapy because of toxicity or intolerance to a specific drug in children with virologic suppression, changing one drug in a multidrug regimen is permissible; if possible, an agent with a different toxicity and side-effect profile should be chosen (AI*).

- The toxicity and the medication presumed responsible should be documented in the medical record and the caregiver and patient advised of the drug-related toxicity (AIII).

- Dose reduction is not a recommended option for management of ARV toxicity, except for those antiretroviral drugs for which a therapeutic range of plasma concentrations detected by therapeutic drug monitoring correlates with toxicity (AII*).

**Rating of Recommendations:** A = Strong; B = Moderate; C = Optional

**Rating of Evidence:** I = One or more randomized trials in children with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

† Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

### Medication Toxicity or Intolerance

The goals of combination antiretroviral therapy (cART) include achieving and maintaining viral suppression and improving immune function, with a regimen that is not only effective but also as tolerable and safe as possible. This requires consideration of the toxicity potential of a cART regimen, as well as the individual child’s underlying conditions, concomitant medications, and prior history of drug intolerances or viral resistance.

Adverse effects have been reported with use of all antiretroviral (ARV) drugs, and are among the most common reasons for switching or discontinuing therapy, and for medication nonadherence. However, rates of treatment-limiting adverse events in ARV-naive patients enrolled in randomized trials or large observational cohorts appear to be declining with increased availability of better-tolerated and less toxic cART regimens and are generally less than 10%. In general, the overall benefits of cART outweigh its risks, and the risk of some abnormal laboratory findings (e.g., anemia, renal impairment) may be lower with cART than in its absence.

ARV drug-related adverse events can vary in severity from mild to severe and life-threatening. Drug-related toxicity can be acute (occurring soon after a drug has been administered), subacute (occurring within 1 to 2 days of administration), or late (occurring after prolonged drug administration). For some ARV medications, pharmacogenetic markers associated with risk of early toxicity have been identified, but the only such screen in routine clinical use is HLA B*5701 as a marker for abacavir hypersensitivity. For selected children aged <3 years who require treatment with efavirenz, an additional pharmacogenetic marker, CYP2B6 genotype, should be assessed (see Efavirenz in Appendix A: Pediatric Antiretroviral Drug Information). For a few other ARV drugs, known therapeutic ranges for plasma concentrations as determined by therapeutic drug monitoring (TDM) may indicate the need for dose reduction or modification of cART in patients experiencing adverse effects (see below and Role of Therapeutic Drug Monitoring in Management of Pediatric HIV Infection).
The most common acute and chronic adverse effects associated with ARV drugs or drug classes are presented in the Management of Medication Toxicity or Intolerance tables. The tables include information on common causative drugs, estimated frequency of occurrence, timing of symptoms, risk factors, potential preventive measures, and suggested clinical management strategies and provide selected references regarding these toxicities in pediatric patients.

**Management**

Management of medication-related toxicity should take into account its severity, the relative need for viral suppression, and the available ARV options. In general, mild and moderate toxicities do not require discontinuation of therapy or drug substitution. However, even mild adverse effects may have a negative impact on medication adherence and should be discussed before therapy is initiated, at regular provider visits, and at onset of any adverse effects. Common, self-limited adverse effects should be anticipated, and reassurance provided that many adverse effects will resolve after the first few weeks of cART. For example, when initiating therapy with boosted protease inhibitors (PIs), many patients experience gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and abdominal pain. Instructing patients to take PIs with food may help minimize these side effects. Some patients may require antiemetics and antidiarrheal agents for symptom management. Central nervous system (CNS) adverse effects are commonly encountered when initiating therapy with efavirenz. Symptoms can include dizziness, drowsiness, vivid dreams, or insomnia. Patients should be instructed to take efavirenz-containing regimens at bedtime, on an empty stomach, to help minimize these adverse effects. They should be advised that these adverse effects usually diminish in general within 2 to 4 weeks of initiating therapy in most people, but may persist for months in some, and may require a medication change. In addition, mild rash can be ameliorated with drugs such as antihistamines. For some moderate toxicities, using a drug in the same class as the one causing toxicity but with a different toxicity profile may be sufficient and discontinuation of all therapy may not be required.

In patients who experience an unacceptable adverse effect from cART, every attempt should be made to identify the offending agent and replace the drug with another effective agent as soon as possible. Many experts will stagger a planned interruption of a non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimen, stopping the NNRTI first and the dual nucleoside analogue reverse transcriptase backbone 7 to 14 days later because of the long half-life of NNRTI drugs. For patients who have a severe or life-threatening toxicity, however, all components of the drug regimen should be stopped simultaneously, regardless of drug half-life. Once the offending drug or alternative cause for the adverse event has been determined, planning can begin for resumption of therapy with a new ARV regimen that does not contain the offending drug or with the original regimen, if the event is attributable to another cause. All drugs in the ARV regimen should then be started simultaneously, rather than one at a time with observation for adverse effects.

When therapy is changed because of toxicity or intolerance in a patient with virologic suppression, agents with different toxicity and side-effect profiles should be chosen, when possible. Clinicians should have comprehensive knowledge of the toxicity profile of each agent before selecting a new regimen. In the event of drug intolerance, changing a single drug in a multidrug regimen is permissible for patients whose viral loads are undetectable. However, substitution of a single active agent for a single drug in a failing multidrug regimen (e.g., a patient with virologic failure) is generally not recommended because of concern for development of resistance (see Recognizing and Managing Antiretroviral Treatment Failure in Management of Children Receiving Antiretroviral Therapy).

TDM may be used in the management of the child with mild or moderate toxicity if the toxicity is thought to be the result of a drug concentration exceeding the normal therapeutic range (see Role of Therapeutic Drug Monitoring). This is the only setting in which dose reduction would be considered appropriate management of drug toxicity, and even then, it should be used with caution; an expert in the management of pediatric HIV infection should be consulted.
To summarize, management strategies for drug intolerance include:

- Symptomatic treatment of mild-to-moderate transient side effects.
- If necessary, change from one drug to another drug to which a patient’s virus is sensitive (such as changing to abacavir for zidovudine-related anemia or to nevirapine for efavirenz-related CNS symptoms).
- Change drug class, if necessary (such as from a PI to a NNRTI or vice versa) and if a patient’s virus is sensitive to a drug in that class.
- Dose reduction only when drug levels are determined excessive.

<td>Exact frequency unknown, but ethanol and propylene glycol toxicity at therapeutic LPV/r dose reported in premature neonates.</td>
<td>Prematurity Low birth weight Age &lt;14 days (whether premature or term)</td>
<td>Avoid use of LPV/r until a postmenstrual age of 42 weeks and a postnatal age ≥14 days.</td>
<td>Discontinue LPV/r; symptoms should resolve in 1–5 days. If needed, reintroduction of LPV/r can be considered once outside the vulnerable period (i.e., postmenstrual age of 42 weeks and a postnatal age ≥14 days).</td>
</tr>
</tbody>
</table>

| Neuropsychiatric Symptoms and Other CNS Manifestations | EFV | Onset:  • 1–2 days after initiating treatment Many symptoms subside or diminish by 2–4 weeks, but may persist in a significant proportion of patients. In one report, 37% experienced persistent symptoms at 12 months and in another, half of discontinuations occurred after 12 months. Presentation May Include One or More of the Following:  • Dizziness  • Somnolence  • Insomnia  • Abnormal dreams  • Impaired concentration  • Psychosis  • Suicidal ideation or | Variable, depending on age, symptom, assessment method Children:  • 24% for any EFV-related CNS manifestations in one case series with 18% requiring drug discontinuation  • 9% (4/44) incidence of new-onset seizures reported in 1 study in children aged <36 months, in two of the children the seizures had alternative causes. Adults:  • >50% for any CNS manifestations of any severity.  • 2% for EFV-related severe CNS manifestations including suicidality. | Insomnia associated with elevated EFV trough concentration ≥4 mcg/mL Presence of CYP450 polymorphisms that decrease EFV metabolism (CYP2B6 516 TT genotype) Prior history of psychiatric illness or use of psychoactive drugs | Administer EFV on an empty stomach, preferably at bedtime. Use with caution in the presence of psychiatric illness including depression or suicidal thoughts or with concomitant use of psychoactive drugs. TDM can be considered in the context of a child with mild or moderate toxicity possibly attributable to a particular ARV agent (see Role of Therapeutic Drug Monitoring in Management of Treatment Failure). | Discontinue EFV if suitable alternative exists |

Consider EFV trough level if symptoms excessive or persistent. If EFV trough level >4 mcg/mL, consider dose reduction, preferably with expert pharmacist input or drug substitution. In a small study, cyproheptadine was shown to reduce short-term incidence of neuropsychiatric effects in adults receiving EFV, but data are lacking in children and no recommendation can be made for its use at this time.

| Intracranial Hemorrhage | TPV | Onset:  
• 7–513 days after starting TPV  
Adults:  
• In premarket approval data in adults, 0.23/100 patient-years or 0.04–0.22/100 patient years in a retrospective review of 2 large patient databases. | Children:  
• No cases of ICH reported in children.  
Adults:  
• In premarket approval data in adults, 0.23/100 patient-years or 0.04–0.22/100 patient years in a retrospective review of 2 large patient databases. | Unknown; prior history of bleeding disorder or risk factors for bleeding present in most patients in case series reported. | Administer TPV with caution in patients with bleeding disorder, known intracranial lesions, or recent neurosurgery. | Discontinue TPV if ICH is suspected or confirmed. |
| Cerebellar Ataxia | RAL | Onset:  
• As early as 3 days after starting RAL  
Presentation:  
• Tremor  
• Dysmetria  
• Ataxia  
Two cases reported in adults during post-marketing period. | Unknown; a speculated mechanism may include recent treatment with ATV with residual UGT1A1 enzyme inhibition and increased RAL serum concentration. | Use with caution with ATV or other drugs that cause strong inhibition of UGT1A1 enzyme. | Consider drug discontinuation. RAL reintroduction can be considered if predisposing factor (e.g., drug-drug interaction) identified and removed. |

**Key to Acronyms:**  
AE = adverse effect; ARV = antiretroviral; ATV = atazanavir; CNS = central nervous system; CYP = cytochrome P; EEG = electroencephalogram; EFV = efavirenz; ICH = intracranial hemorrhage; LPV/r = ritonavir-boosted lopinavir; PPI = proton pump inhibitor; RAL = raltegravir; RPV = rilpivirine; TDF = tenofovir disoproxyl fumarate; TDM = therapeutic drug monitoring; TPV = tipranavir; UGT = uridine diphosphate-glucurononyl transferase

<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Children Receiving Lipid-Lowering Therapy with Statins or Fibrates:</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>The minimal goal of therapy should be to achieve and maintain a LDL-C value below 130 mg/dL. Initiate Drug Therapy Promptly in Patients with Fasting TG ≥500 mg/dL:</td>
</tr>
<tr>
<td>• Obtain 12-hour FLP, LFTs, and CK at 4 and 8 weeks, and 3 months after starting lipid therapy.</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>Statins such as pravastatin, atorvastatin, or rosuvastatin. Ezetimibe can be considered in addition to statins. Statin-related toxicities include liver enzyme elevation and myopathy, and risk may be increased by drug interactions with cART, particularly PIs. Risks must be weighed against potential benefits.</td>
</tr>
<tr>
<td>• If minimal alterations in AST, ALT, and CK, monitor every 3–4 months in the first year and every 6 month thereafter (or as clinically indicated).</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>Fibrates (gemfibrozil and fenofibrate) and N-3 PUFAs derived from fish oils may be used as alternative agents for adults with TG but are not approved for use in children. The long-term risks of lipid abnormalities in children receiving cART are unclear. However, persistent dyslipidemia in children may lead to premature CVD.</td>
</tr>
<tr>
<td>• Repeat FLPs 4 weeks after increasing doses of antihyperlipidemic agents.</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\(^a\) Given the burden of collecting fasting blood samples, some practitioners routinely measure cholesterol and triglycerides from non-fasting blood samples and follow up abnormal values with a test done in the fasted state.

\(^c\) The risks of new treatment-related toxicities and virologic failure that could occur with changes in therapy must be weighed against the potential risk of drug interactions and toxicities associated with the use of lipid-lowering agents.

\(^d\) Statins (HMG-CoA reductase inhibitors) are contraindicated in pregnancy (potentially teratogenic) and should not be used in patients who may become pregnant. Multiple drug interactions exist between ARV drugs and statins (exception pravastatin, which is not dependent on CYP3A4 for metabolism). Pravastatin, atorvastatin, rosuvastatin (Crestor®),
fluvastatin, and ezetimibe (Zetia®) are approved for use in children aged ≥10 years.

Key to Acronyms: ALT = alanine aminotransferase; ART = antiretroviral therapy; ARV = antiretroviral; AST = aspartate aminotransferase; ATV = atazanavir; cART = combination antiretroviral therapy; CK = creatine kinase; CVD = cardiovascular disease; CYP3A4 = cytochrome P450 3A4; d4T = stavudine; DRV = darunavir; DRV/r = ritonavir-boosted darunavir; EFV = efavirenz; ETR = etravirine; FLP = fasting lipid profile; HDL-C = high-density lipoprotein cholesterol; LDL-C = low-density lipoprotein cholesterol; LFT = liver function test; LPV = lopinavir; NHLBI = National Heart, Lung, and Blood Institute; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; PUFA = polyunsaturated fatty acid; RPV = rilpivirine; RTV = ritonavir; TC = total cholesterol; TG = triglyceride

<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Nausea/Vomiting</strong></td>
<td>Principally ZDV and PIs (e.g., LPV/r, RTV), but can occur with all ARVs</td>
<td>Onset: • Early Presentation: • Nausea, emesis—may be associated with anorexia and/or abdominal pain.</td>
<td>Varies with ARV agent; 10% to 30% in some series</td>
<td>Unknown</td>
<td>Instruct patient to take PIs with food. Generally improves with time; monitor for weight loss, ARV adherence.</td>
<td>Reassure patient/caretaker that nausea and vomiting will likely decrease over time. Provide supportive care, including instruction on dietary modification. Although antiemetics are not generally indicated, they may be useful in extreme or persistent cases.</td>
</tr>
<tr>
<td><strong>Diarrhea</strong></td>
<td>PIs <em>(particularly NPV, LPV/r, FPV/r)</em>, buffered ddl, INSTI</td>
<td>Onset: • Early Presentation: • Generally soft, more frequent stools</td>
<td>Varies with ARV agent; 10% to 30% in some series</td>
<td>Unknown</td>
<td>Generally improves with time (usually over 6–8 weeks); monitor for weight loss, dehydration.</td>
<td>Exclude infectious causes of diarrhea. Although data in children on treatment of ARV-associated diarrhea are lacking, dietary modification, use of calcium carbonate <em>(should not be used with DTG)</em>, bulk-forming agents (psyllium), or antimotility agents (loperamide) may be helpful. While there are few published data on its use, crofelemer is FDA-approved for treatment of ART-associated diarrhea in adults but <em>not</em> in children.</td>
</tr>
<tr>
<td><strong>Pancreatitis</strong></td>
<td>ddl, d4T (especially concurrently or with TDF), boosted PIs Reported, albeit rarely, with most ARVs</td>
<td>Onset: • Any time, usually after months of therapy Presentation: • Emesis, abdominal pain, elevated amylase and lipase (Asymptomatic hyperamylasemia or elevated lipase do not in and of themselves indicate pancreatitis.)</td>
<td>&lt;2% in recent series. Frequency was higher in the past with higher dosing of ddl.</td>
<td>Concomitant treatment with other medications associated with pancreatitis (e.g., TMP-SMX, pentamidine, ribavirin) Hypertriglyceridemia Advanced disease Previous episode of pancreatitis Avoid use of ddl in patients with a history of pancreatitis.</td>
<td>Discontinue offending agent—avoid reintroduction. Manage symptoms of acute episode. If associated with hypertriglyceridemia, consider interventions to lower TG levels.</td>
<td></td>
</tr>
</tbody>
</table>

**Key to Acronyms:** ART = antiretroviral therapy; ARV = antiretroviral; d4T = stavudine; ddl = didanosine; DTG = dolutegravir; FDA = Food and Drug Administration; FPV/r = fosamprenavir/ritonavir; LPV/r = ritonavir-boosted lopinavir; NFV = nevirapine; PI = protease inhibitor; RTV = ritonavir; TDF = tenofovir disoproxil fumarate; TG = triglyceride; TMP-SMX = trimethoprim sulfamethoxazole; ZDV = zidovudine

### Table 13d. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations—Hematologic Effects  
(Last updated March 5, 2015; last reviewed March 5, 2015)  
(page 1 of 2)

<table>
<thead>
<tr>
<th>Adverse Effects</th>
<th>Associated ARVs</th>
<th>Onset/Clinical Manifestations</th>
<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/Monitoring</th>
<th>Management</th>
</tr>
</thead>
</table>
| **Anemia**<sup>a</sup> | Principally ZDV | Onset:  
• Variable, weeks to months  
Presentation:  
*Most Commonly:*  
• Asymptomatic or mild fatigue  
• Pallor  
• Tachypnea  
*Rarely:*  
• Congestive heart failure | HIV-Exposed Newborns:  
• Severe anemia is uncommon, but may be seen coincident with physiologic Hgb nadir.  
HIV-Infected Children on ARVs:  
• 2–3 times more common with ZDV-containing regimens; less frequent with currently recommended dosing of ZDV | HIV-Exposed Newborns:  
• Premature birth  
• *In utero* exposure to ARVs  
• Advanced maternal HIV  
• Neonatal blood loss  
• Concurrent ZDV plus 3TC neonatal prophylaxis | HIV-Exposed Newborns:  
• Obtain CBC at birth.  
• Consider repeat CBC at 4 weeks for neonates who are at higher risk (e.g., those born prematurely or known to have low birth Hgb).  
HIV-Infected Children on ARVs:  
• Avoid ZDV in children with moderate to severe anemia when alternative agents are available.  
• Obtain CBC as part of routine care. | HIV-Exposed Newborns:  
• Rarely require intervention unless Hgb is <7.0 g/dL or anemia is associated with symptoms.  
• Consider discontinuing ZDV if 4 weeks or more of a 6-week ZDV prophylaxis regimen are already completed (see the Perinatal Guidelines<sup>a</sup>).  
HIV-Infected Children on ARVs:  
• Discontinue non-ARV, marrow-toxic drugs, if feasible.  
• Treat coexisting iron deficiency, OIs, malignancies.  
• For persistent severe anemia thought to be associated with ARVs, change to a non-ZDV-containing regimen; consider a trial of erythropoietin if essential to continue ZDV. |
| **Macrocytosis** | Principally ZDV; also d4T | Onset:  
• Within days to weeks of starting therapy  
• MCV often >100 fL  
Presentation:  
• Most often asymptomatic  
• Sometimes associated with anemia (occurs more often with ZDV than with d4T) | >90% to 95%, all ages | None | Obtain CBC as part of routine care. | None required unless associated with anemia |

<td><strong>Hepatic Toxicity</strong></td>
<td>Elevated AST, ALT, clinical hepatitis</td>
<td>Onset:</td>
<td>Symptomatic patients</td>
<td>Prevention:</td>
<td>Management</td>
<td>Asymptomatic patients</td>
</tr>
<tr>
<td></td>
<td>All ARVs may be associated with hepatitis. NVP and TPV are of particular concern.</td>
<td>Elevated baseline ALT and AST</td>
<td></td>
<td>Avoid concomitant use of hepatotoxic medications.</td>
<td>Some would consider discontinuing ARVs.</td>
<td>with elevated ALT or AST should be evaluated for other causes and monitored closely. If ALT or AST is more than 5–10 times ULN, some would consider discontinuing ARVs.</td>
</tr>
<tr>
<td></td>
<td>NVP, EFV, ABC, RAL, and MVC have been associated with hypersensitivity reactions.</td>
<td>Other hepatotoxic medications (including herbal preparations such as St. John’s wort)</td>
<td></td>
<td>If hepatic enzymes are elevated &gt;5 to 10 times ULN or chronic liver disease, most clinicians</td>
<td>Prevention:</td>
<td>In symptomatic patients, discontinue all ARVs and other potential hepatotoxic agents and avoid restarting the offending agent.</td>
</tr>
<tr>
<td></td>
<td>NRTIs (especially ZDV, ddl, and d4T) are associated with lactic acidosis and hepatic steatosis.</td>
<td>Elevated baseline ALT and AST</td>
<td></td>
<td>would avoid NVP.</td>
<td>Monitoring:</td>
<td>If a symptomatic hepatic event occurs on NVP, permanently discontinue drug (see also NVP Hypersensitivity).</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Other hepatotoxic medications (including herbal preparations such as St. John’s wort)</td>
<td></td>
<td></td>
<td></td>
<td>When clinical hepatitis is associated with lactic acidosis, avoid restarting the most likely agent, including ZDV, d4T, and ddl in particular (see also Lactic Acidosis).</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Elevated baseline ALT and AST</td>
<td></td>
<td></td>
<td></td>
<td>Consider viral causes of hepatitis: HAV, HBV, HCV, EBV, and CMV.</td>

* Insulin resistance, asymptomatic hyperglycemia, and DM form a spectrum of increasing severity. **Insulin resistance** is often defined as elevated insulin levels for the level of glucose observed; **impaired FPG** as an FPG of 100–125 mg/dL; **impaired glucose tolerance** as an elevated 2-hour PG of 140–199 mg/dL in a standard OGTT; and **diabetes mellitus** as either an FPG ≥126 mg/dL, a random PG ≥200 mg/dL in a patient with hyperglycemia symptoms, an HgbA1C of ≥6.5%, or a 2-hour PG after OGTT ≥200 mg/dL. However, the Panel does not recommend routine determinations of insulin levels, HgbA1C, or glucose tolerance without consultation with an endocrinologist; these guidelines are instead based on the readily available random and fasting plasma glucose levels.

**Key to Acronyms:** ABC = abacavir; ARV = antiretroviral; ATV = atazanavir; ATV/r = ritonavir-boosted atazanavir; BMI = body mass index; d4T = stavudine; ddi = didanosine; DM = diabetes mellitus; DRV/r = ritonavir-boosted darunavir; FPG = fasting plasma glucose; HgbA1c = glycosylated hemoglobin; LPV/r = ritonavir-boosted lopinavir; NFV = nefillinavir; NRTI = nucleoside reverse transcriptase inhibitor; OGTT = oral glucose tolerance test; PG = plasma glucose; PI = protease inhibitor; RPG = random plasma glucose; TDF = tenofovir disoproxil fumarate; TPV/r = ritonavir-boosted tipranavir; ZDV = zidovudine

### Table 13g. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations—Lactic Acidosis

**Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection**

<table>
<thead>
<tr>
<th>Adverse Effects</th>
<th>Associated ARVs</th>
<th>Onset/Clinical Manifestations</th>
<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lactic Acidosis</td>
<td>NRTIs, in particular, d4T and ddl (highest risk in combination)</td>
<td>Onset: 1–20 months after starting therapy (median onset 4 months in 1 case series)</td>
<td>Chronic, Asymptomatic Mild Hyperlactatemia (&gt;2.1–5.0 mmol/L): Adults: 15% to 35% of adults receiving NRTI therapy for longer than 6 months</td>
<td>Adults: Female gender, High BMI, Chronic HCV infection, African-American race, Prolonged NRTI use (particularly d4T and ddl), Co-administration of ddl with other agents (e.g., d4T, TDF, RBV, tetracycline), Co-administration of TDF with metformin, Overdose of propylene glycol, CD4 count &lt;350 cells/mm³, Acquired riboflavin or thiamine deficiency, Possibly pregnancy</td>
<td>Avoid d4T and ddl individually and especially in combination in an ARV regimen. Monitor for clinical manifestations of lactic acidosis and promptly adjust therapy.</td>
<td>Lactate 2.1–5.0 mmol/L (Confirmed with Second Test): Consider replacing ddl and d4T with other ARVs. As an alternative, temporarily discontinue all ARVs while conducting additional diagnostic workup. Lactate &gt;5.0 mmol/L (Confirmed with Second Test) or &gt;10.0 mmol/L (Any 1 Test): Discontinue all ARVs. Provide supportive therapy (IV fluids; some patients may require sedation and respiratory support to reduce oxygen demand and ensure adequate oxygenation of tissues). Anecdotal (Unproven) Supportive Therapies: Bicarbonate infusions, THAM, high-dose thiamine and riboflavin, oral antioxidants (e.g., L-carnitine, co-enzyme Q10, vitamin C) Following resolution of clinical and laboratory abnormalities, resume therapy, either with an NRTI-sparing regimen or a revised NRTI-containing regimen instituted with caution, using NRTIs less likely to inhibit mitochondria (ABC or TDF preferred; possibly FTC or 3TC), and monthly monitoring of lactate for at least 3 months.</td>
</tr>
</tbody>
</table>

**Note:** Patients may present with acute multi-organ failure (such as fulminant hepatic, pancreatic, and respiratory failure).

**Presentation:** Usually Insidious Onset of a Combination of Signs and Symptoms:
- Generalized fatigue, weakness, and myalgias
- Vague abdominal pain, weight loss, unexplained nausea or vomiting
- Dyspnea
- Peripheral neuropathy

**Risk Factors:**
- Female gender
- High BMI
- Chronic HCV infection
- African-American race
- Prolonged NRTI use (particularly d4T and ddl)
- Co-administration of ddl with other agents (e.g., d4T, TDF, RBV, tetracycline)
- Co-administration of TDF with metformin
- Overdose of propylene glycol
- CD4 count <350 cells/mm³
- Acquired riboflavin or thiamine deficiency
- Possibly pregnancy

**Prevention:**
- Avoid d4T and ddl individually and especially in combination in an ARV regimen.
- Monitor for clinical manifestations of lactic acidosis and promptly adjust therapy.

**Monitoring:**
- Asymptomatic:
  - Measurement of serum lactate is not recommended.
  - Clinical Signs or Symptoms Consistent with Lactic Acidosis:
    - Obtain blood lactate level; additional diagnostic evaluations should include serum bicarbonate and anion gap and/or arterial blood gas, amylase and lipase, serum albumin, and hepatic transaminases.

**Management:**
- Lactate 2.1–5.0 mmol/L (Confirmed with Second Test): Consider replacing ddl and d4T with other ARVs. As an alternative, temporarily discontinue all ARVs while conducting additional diagnostic workup. Lactate >5.0 mmol/L (Confirmed with Second Test) or >10.0 mmol/L (Any 1 Test): Discontinue all ARVs. Provide supportive therapy (IV fluids; some patients may require sedation and respiratory support to reduce oxygen demand and ensure adequate oxygenation of tissues).
- Anecdotal (Unproven) Supportive Therapies: Bicarbonate infusions, THAM, high-dose thiamine and riboflavin, oral antioxidants (e.g., L-carnitine, co-enzyme Q10, vitamin C)
- Following resolution of clinical and laboratory abnormalities, resume therapy, either with an NRTI-sparing regimen or a revised NRTI-containing regimen instituted with caution, using NRTIs less likely to inhibit mitochondria (ABC or TDF preferred; possibly FTC or 3TC), and monthly monitoring of lactate for at least 3 months.

---

**Key to Acronyms:**
- 3TC = lamivudine; ABC = abacavir; ARV = antiretroviral; BMI = body mass index; CD4 = CD4 T lymphocyte; d4T = stavudine; ddl = didanosine; FTC = emtricitabine; HCV = hepatitis C virus; IV = intravenous; LPV/r = ritonavir-boosted lopinavir; NRTI = nucleoside reverse transcriptase inhibitor; RBV = ribavirin; TDF = tenofovir disoproxil fumarate; THAM = tris (hydroxymethyl) aminomethane

### Management

### Table 13i. Antiretroviral Therapy-Associated Adverse Effects and Management Recommendations—Nephrotoxic Effects

*Last updated March 5, 2015; last reviewed March 5, 2015*  
*(page 1 of 2)*

<table>
<thead>
<tr>
<th>Adverse Effects</th>
<th>Associated ARVs</th>
<th>Onset/Clinical Manifestations</th>
<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
</table>
| **Urolithiasis/ Nephrolithiasis** | ATV | Onset:  
- Weeks to months after starting therapy  
Clinical Findings:  
- Crystalluria, hematuria, pyuria, flank pain, sometimes increased creatinine  
ATV-related nephrolithiasis occurs in <10%.  
In adults, elevated urine pH (>5.7)  
Unknown in children | Prevention:  
- Maintain adequate hydration.  
Monitoring:  
- Obtain urinalysis at least every 6–12 months. | Provide adequate hydration and pain control; consider using alternative ARV. |
| **Renal Dysfunction** | TDF | Onset:  
- Variable; in adults, weeks to months after initiation of therapy.  
- Hypophosphatemia appears at a median of 18 months.  
- Glucosuria may have onset after a year of therapy.  
Presentation:  
More Common:  
- Increased serum creatinine, proteinuria, normoglycemic glucosuria. Hypophosphatemia, usually asymptomatic; may present with bone and muscle pain, weakness.  
Less Common:  
- Renal failure, acute tubular necrosis, Fanconi syndrome, proximal renal tubulopathy, interstitial nephritis, nephrogenic diabetes insipidus with polyuria  
Risk May Be Increased in Children:  
- Aged >6 years  
- Of black race, Hispanic / Latino ethnicity  
- With advanced HIV infection  
- With concurrent use of ddi or PIs (especially LPV/r), and preexisting renal dysfunction  
- Risk increases with longer duration of TDF treatment. | Monitor urine protein and glucose or urinalysis, and serum creatinine at 3- to 6-month intervals. For patients taking TDF, some panelists add serum phosphate to the list of routine labs to monitor.  
In the presence of persistent proteinuria or glucosuria, or for symptoms of bone pain or muscle pain or weakness, also monitor serum phosphate.  
Because toxicity risk increases with duration of TDF treatment, frequency of monitoring should not decrease with time. While unproven, routine monitoring intervals of every 3–6 months might be considered. Abnormal values should be confirmed by repeat testing, and frequency of monitoring can be increased if abnormalities are found and TDF is continued. | If TDF is the likely cause, consider using alternative ARV. |

| Elevation in Serum Creatinine | DTG, COBI, RPV | Onset:  
• Within a month of starting treatment  
Presentation:  
• Asymptomatic. These drugs decrease renal tubular secretion of creatinine, leading to an increase in measured serum creatinine without a true change in GFR. | Common  
Need to distinguish between true change in GFR and other causes | Monitor serum creatinine. Assess for renal dysfunction if serum creatinine increases by >0.4 mg/dL. | No need to change therapy. Reassure patient about the benign nature of the laboratory abnormality. |

Key to Acronyms: ARV = antiretroviral; ATV = atazanavir; COBI = cobicistat; ddI = didanosine; DRV = darunavir; DTG = dolutegravir; GFR = glomerular filtration rate; LPV/r = ritonavir-boosted lopinavir; PI = protease inhibitor; RPV = ritonavir; TDF = tenofovir disoproxil fumarate

<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Osteopenia and Osteoporosis</td>
<td>Any cART regimen</td>
<td>Onset: • Any age; more common in months after initiation of cART.</td>
<td>Low BMD: • 7% of a U.S. cohort had a BMD z score of ≤ -2.0 (87% treated with cART).</td>
<td>Longer duration of HIV infection Greater severity of HIV disease Growth delay, pubertal delay Low BMI Lipodystrophy Non-black race Smoking Prolonged systemic corticosteroid use Medroxyprogesterone use Minimal weight-bearing exercise</td>
<td>Prevention: • Ensure sufficient calcium and vitamin D intake. • Encourage weight-bearing exercise. • Minimize modifiable risk factors (e.g., smoking, low BMI, steroid use). Monitoring: • Obtain serum 25-OH-vitamin D.a • Obtain DXA.a</td>
<td>Ensure sufficient calcium and vitamin D intake. Encourage weight-bearing exercise. Reduce modifiable risk factors (e.g., smoking, low BMI, use of steroids, use of medroxyprogesterone). Role of bisphosphonates not established in children Consider change in ARV regimen.</td>
</tr>
<tr>
<td>Specific Agents of Possible Concern: • TDF • PIs, especially LPV/r</td>
<td>Presentation: • Most commonly asymptomatic; fracture (rare).</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Osteoporosis diagnosis in children requires clinical evidence of bone fragility (e.g., fracture with minimal trauma) and cannot rely solely on measured low BMD.</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

a Some experts would periodically measure 25-OH-vitamin D, especially in HIV-infected urban youth because, in this population, the prevalence of vitamin D insufficiency is high.

b Until more data are available about the long-term effects of TDF on bone mineral acquisition in childhood, some experts would obtain a DXA at baseline and every 6 to 12 months for prepubertal children and children in early puberty who are initiating treatment with TDF. DXA should also be considered in adolescent women on TDF and medroxyprogesterone and in children with indications not uniquely related to HIV infection (such as cerebral palsy).

**Key to Acronyms:** ARV = antiretroviral; BMD = bone mineral density; BMI = body mass index; cART = combination antiretroviral therapy; DXA = dual-energy x-ray absorptiometry; LPV/r = ritonavir-boosted lopinavir; PI = protease inhibitor; TDF = tenofovir disoproxil fumarate

<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
</table>
| Rash           | Any ARV can cause rash. | Onset:  
• First few days to weeks after starting therapy | Common (>10% Adults and/or Children):  
• NVP, EFV, ETR, FPV, FTC  
Less Common (5% to 10%):  
• ABC, DRV, TPV, TDF  
Unusual (2% to 4%):  
• LPV/r, RAL, MVC, RPV | • Sulfonamide allergy is a risk factor for rash with PIs containing a sulfonamide moiety (FPV, DRV, and TPV).  
• Possible association of polymorphisms in CYP2B6 and multiple HLA loci with rash with NVP. | When Starting NVP or Restarting After Interruptions >14 Days:  
• Once-daily dosing (50% of total daily dose) for 2 weeks, then escalation to target dose with twice-daily dosing is associated with fewer rashes.  
• Avoid the use of systemic corticosteroids during NVP dose escalation.  
• Assess patient for rash severity, mucosal involvement, and other signs of systemic reaction.  
• Consider concomitant medications and illnesses that cause rash. | Mild-To-Moderate Maculopapular Rash Without Systemic or Mucosal Involvement:  
• Most will resolve without intervention; ARVs can be continued while monitoring.  
• Antihistamines may provide some relief.  
Severe Rash (e.g., Blisters, Bullae, Ulcers, Skin Necrosis) and/or Rash Accompanied by Systemic Symptoms (e.g., Fever, Arthralgias, Edema) and/or Rash Accompanied By Mucous Membrane Involvement (e.g., Conjunctivitis):  
• Manage as SJS/TEN/EM Major (see below).  
Rash in Patients Receiving NVP:  
• Given elevated risk of HSR, measure hepatic transaminases.  
• If hepatic transaminases are elevated, NVP should be discontinued and not restarted (see HSR-NVP).  
| ENF            |                | Onset:  
• First few days to weeks after starting therapy | Adults and Children:  
• >90% | Unknown | Routinely assess patient for local reactions.  
• Rotate injection sites.  
• Massage area after injection. | Continue the agent as tolerated by the patient.  
• Adjust injection technique.  
• Rotate injection sites. |

<table>
<thead>
<tr>
<th>Adverse Effects</th>
<th>Associated ARVs</th>
<th>Onset/Clinical Manifestations</th>
<th>Estimated Frequency</th>
<th>Risk Factors</th>
<th>Prevention/ Monitoring</th>
<th>Management</th>
</tr>
</thead>
</table>
| SJS/TEN/EM Major | Many ARVs, especially NNRTIs (see frequency column) | Onset:  
  • First few days to weeks after initiating therapy  
  Presentation:  
  • Initial rash may be mild, but often becomes painful, evolving to blister/bulla formation with necrosis in severe cases. Usually involves mucous membrane ulceration and/or conjunctivitis. Systemic symptoms may include fever, tachycardia, malaise, myalgia, and arthralgia. | Infrequent:  
  • NVP (0.3%), EFV (0.1%), ETR (<0.1%)  
  Case Reports:  
  • FPV, ABC, DRV, ZDV, ddI, IDV, LPV/r, ATV, RAL | Adults:  
  • Female gender  
  • Race/ethnicity (black, Asian, Hispanic) | To Lower the Risk of Reactions to NVP when Starting or Restarting after Interruptions >14 Days:  
  • Utilize once-daily dosing (50% of total daily dose) for 2 weeks, then escalate to target dose with twice-daily dosing, which is associated with fewer rashes.³  
  • Counsel families to report symptoms as soon as they appear. |  
  • Discontinue all ARVs and other possible causative agents such as cotrimoxazole.  
  • Provide intensive supportive care, IV hydration, aggressive wound care, pain management, antipyretics, parenteral nutrition, and antibiotics as needed in case of superinfection.  
  • Corticosteroids and/or IVIG are sometimes used, but use of each is controversial.  
  • Do not reintroduce the offending medication.  
  • In case of SJS/TEN/EM major with one NNRTI, many experts would avoid use of other NNRTIs. |
| Systemic HSR | ABC | Onset  
  *With First Use:*  
  • Within first 6 weeks  
  *With Re-Introduction:*  
  • Within hours  
  Presentation:  
  • Symptoms include high fever, diffuse skin rash, malaise, nausea, headache, myalgia, arthralgia, diarrhea, vomiting, abdominal pain, pharyngitis, respiratory symptoms (e.g., dyspnea).  
  • Symptoms worsen to include hypotension and vascular collapse with continuation. With re-challenge, symptoms can mimic anaphylaxis. | 2.3% to 9% (varies by racial/ethnic group). |  
  • HLA-B*5701 (HSR very uncommon in people who are HLA-B*5701-negative); also HLA-DR7, HLA-DQ3.  
  • HSR risk is higher in those of white race compared to those of black or East Asian race. | Screening for HLA-B*5701. *ABC should not be prescribed if HLA-B*5701 is positive.* The medical record should clearly indicate that ABC is contraindicated.  
  • When starting ABC, counsel patients and families about the signs and symptoms of HSR to ensure prompt reporting of reactions. |  
  • Discontinue ARVs and investigate for other causes of the symptoms (e.g., a concurrent viral illness).  
  • Treat symptoms as necessary.  
  • Most symptoms resolve within 48 hours after discontinuation of ABC.  
  • Do not re-challenge with ABC even if the patient is HLA-B*5701-negative. |

*The prescribing information for NVP states that patients experiencing rash during the 14-day lead-in period should not have the NVP dose increased until the rash has resolved. However, prolonging the lead-in phase beyond 14 days may increase risk of NVP resistance because of sub-therapeutic drug levels. Management of children who have persistent mild or moderate rash after the lead-in period should be individualized and consultation with an expert in HIV care should be obtained. **NVP should be stopped and not restarted** if the rash is severe or is worsening or progressing.*

### References

In the United States, the majority of HIV-infected children are receiving combination antiretroviral therapy (cART), making treatment-experienced children the norm. Changes in the antiretroviral (ARV) regimen and other aspects of the management of treatment-experienced children can be organized into the following categories:

1. Modifying ARV regimens in children on effective cART for simplification or improved adverse effect profile;
2. Recognizing and managing ARV drug toxicity or intolerance (see Management of Medication Toxicity or Intolerance);
3. Recognizing and managing treatment failure; and
4. Considerations about interruptions in therapy.

Modifying Antiretroviral Regimens in Children with Sustained Virologic Suppression on Antiretroviral Therapy

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children\textsuperscript{†} with clinical outcomes and/or validated endpoints; 1\textsuperscript{*} = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children\textsuperscript{†} from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children\textsuperscript{†} with long-term outcomes; II\textsuperscript{*} = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children\textsuperscript{†} from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

\textsuperscript{†} Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

Initial ARV regimens are chosen based on safety, pharmacokinetic and efficacy data for drugs available in formulations suitable for the age of the child at initiation of cART. New ARV options may become available as children grow and learn to swallow pills and as new drugs, drug formulations, and data become available. For children who have sustained virologic suppression (e.g., 6–12 months) on their current regimen, changing to a new ARV regimen may be considered in order to permit use of pills instead of liquids, reduce pill burden, allow use of once-daily medications, reduce risk of adverse effects, and align their regimens with widely used, efficacious adult regimens.

Several studies have addressed switching ARV regimen components in children with sustained virologic suppression. Based on the NEVEREST study, young children (aged <3 years) with virologic suppression who switch from lopinavir/ritonavir to nevirapine can maintain virologic suppression as well as those who continue lopinavir/ritonavir, provided there is good adherence and no baseline resistance to nevirapine.\textsuperscript{1,2} In the NEVEREST 3 study, young children with history of exposure to nevirapine and with virologic suppression on lopinavir/ritonavir maintained virologic suppression when switched from lopinavir/ritonavir to efavirenz.\textsuperscript{3} By extrapolation, replacement of lopinavir/ritonavir with an equally potent protease inhibitor (PI) (e.g., darunavir, atazanavir), raltegravir, or another integrase inhibitor (INSTI) would likely be effective, but this has not been directly studied. Several small studies have demonstrated sustained virologic suppression and reassuring safety outcomes when drugs that have greater long-term toxicity risk are replaced with drugs that are thought to have less toxicity risk (e.g., replacing stavudine with tenofovir disoproxil fumarate, zidovudine, or abacavir;
replacing PIs with non-nucleoside reverse transcriptase inhibitors), including improved lipid profiles, in small
cohorts of children.4-8 Small studies have shown that children with virologic suppression on certain twice-daily
regimens (i.e., abacavir, nevirapine) maintain virologic suppression if changed from twice daily to once daily
(see Abacavir and Nevirapine drug sections) but show mixed results when switching lopinavir/ritonavir dosing
from twice daily to once daily; therefore, once-daily lopinavir/ritonavir is not recommended.9-11

Table 14 displays examples of changes in ARV regimen components that are made for reasons of
simplification, convenience, and safety profile in children who have sustained virologic suppression on their
current regimen. When considering such a change, it is important to ensure that a child does not have virologic
treatment failure. It is also critical to consider past episodes of ARV treatment failure, tolerability, and all prior
drug resistance testing results in order to avoid choosing new ARV drugs for which archived drug resistance
would limit activity. The evidence supporting many of these ARV changes is indirect, extrapolated from data
about drug performance in initial therapy or follow-on therapy after treatment failure. When such changes are
made, careful monitoring is important to ensure that virologic suppression is maintained.

**Definitions of Treatment Failure**

Treatment failure can be categorized as virologic failure, immunologic failure, or clinical failure (or some combination of the three). Laboratory results must be confirmed with repeat testing before a final assessment of virologic or immunologic treatment failure is made. Almost all antiretroviral (ARV) management decisions for treatment failure are based on addressing virologic failure.

**Virologic Failure**

Virologic failure occurs as an incomplete initial response to therapy or as a viral rebound after virologic suppression is achieved. Virologic suppression is defined as having plasma viral load below the lower level of quantification (LLQ) using the most sensitive assay (LLQ 20–75 copies/mL). Older assays with LLQ of 400 copies/mL are not recommended. **Virologic failure** is defined for all children as a repeated plasma viral load >200 copies/mL after 6 months of therapy. Because infants with high plasma viral loads at initiation of therapy occasionally take longer than 6 months to achieve virologic suppression, some experts continue the treatment regimen for such infants if viral load is declining but is still >200 copies/mL at 6 months and monitor closely for continued decline to virologic suppression soon thereafter. Among many of those receiving lopinavir/ritonavir, suppression can be achieved without regimen change if efforts are made to improve adherence.¹ However, ongoing non-suppression—especially with non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimens—increases the risk of drug resistance.² There is controversy regarding the clinical implications of HIV RNA levels between the LLQ and <200 copies/mL in patients on...
Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

combination antiretroviral therapy (cART). HIV-infected adults with detectable viral loads and a quantified result <200 copies/mL after 6 months of cART often ultimately achieve virologic suppression without regimen change.3 “Blips,” defined as isolated episodes of plasma viral load detectable at low levels (<500 copies/mL) followed by return to viral suppression, are common and not generally reflective of virologic failure.4-6 Repeated or persistent plasma viral load detection above 200 copies/mL (especially if >500 copies/mL) after having achieved virologic suppression usually represents virologic failure.6-9

Immunologic Failure

Immunologic failure is defined as a suboptimal immunologic response to therapy or an immunologic decline while on therapy. While there is no standardized definition, many experts would consider as suboptimal immunologic response to therapy the failure to maintain or achieve a CD4 T lymphocyte (CD4) cell count/percentage that is at least above the age-specific range for severe immunodeficiency. Evaluation of immune response in children is complicated by the normal age-related changes in CD4 cell count discussed previously (see Immunologic Monitoring in Children: General Considerations in Clinical and Laboratory Monitoring). Thus, the normal decline in CD4 values with age needs to be considered when evaluating declines in CD4 parameters. CD4 percentage tends to vary less with age. At about age 5 years, absolute CD4 cell count values in children approach those of adults; consequently, changes in absolute count can be used in children aged ≥5 years.

Clinical Failure

Clinical failure is defined as the occurrence of new opportunistic infections (OIs) and/or other clinical evidence of HIV disease progression during therapy. Clinical failure represents the most urgent and concerning type of treatment failure and should prompt an immediate evaluation. Clinical findings should be viewed in the context of virologic and immunologic response to therapy; in patients with stable virologic and immunologic parameters, development of clinical symptoms may not represent treatment failure. Clinical events occurring in the first several months after cART initiation often do not represent cART failure. For example, the development or worsening of an OI in a patient who recently initiated cART may reflect a degree of persistent immune dysfunction in the context of early recovery or, conversely, be a result of immune reconstitution inflammatory syndrome (IRIS). However, clinical failure may occur many months after CD4 cell counts have normalized.10 The occurrence of significant clinical disease progression should prompt strong consideration that the current treatment regimen is failing.

Discordance Between Virologic, Immunologic, and Clinical Responses

In general, cART that results in virologic suppression also leads to immune restoration or preservation as well as to prevention of HIV-related illnesses. The converse is also generally true: Ineffective cART that fails to suppress viremia is commonly accompanied by immunologic and clinical failure.11 However, patients may also present with discordant responses, with failure in one domain (e.g., immunologic failure) but with a good response in the other domains (e.g., virologic and clinical response). It is essential to consider potential alternative causes of discordant responses before concluding that cART failure has truly occurred.

Poor Immunologic Response Despite Virologic Suppression

Poor immunologic response despite virologic suppression is uncommon in children.10 For patients with baseline severe immunosuppression, virologic suppression may be achieved much sooner than immune recovery. During this early treatment period of persistent immunosuppression, additional clinical disease progression can occur.

The first considerations in cases of poor immunologic response despite virologic suppression are to exclude laboratory error in CD4 or viral load measurements and to ensure that CD4 values have been interpreted correctly in relation to the natural decline in CD4 cell count over the first 5 to 6 years of life. Another laboratory consideration is that some viral load assays may not amplify all HIV groups and subtypes (such as
HIV-1 non-M groups or HIV-2), resulting in falsely low or negative viral load results (see Diagnosis of HIV Infection and Clinical and Laboratory Monitoring). Once laboratory results are confirmed, evaluation for adverse drug effects, medical conditions, and other factors that can result in lower CD4 values is necessary (see Table 15).

Patients who have very low baseline CD4 values before initiating cART are at higher risk of an impaired CD4 response to cART and, based on adult studies, may be at higher risk of death and AIDS-defining illnesses, despite virologic suppression. In a study of 933 children aged ≥5 years who received cART that resulted in virologic suppression, 92 (9.9%) had CD4 cell counts <200 cells/mm³ at cART initiation and 348 (37%) had CD4 cell counts <500 cells/mm³. After 1 year of virologic suppression, only 7 (1% of the cohort) failed to reach a CD4 cell count of at least 200 cells/mm³ and 86% had CD4 cell counts >500 cells/mm³. AIDS-defining events were uncommon overall (1%) but occurred in children who did and did not achieve improved CD4 cell counts.10

Certain ARV agents or combinations may be associated with a blunted CD4 response. For example, treatment with a regimen containing tenofovir disoproxil fumarate (tenofovir) and didanosine can blunt the CD4 response, especially if the didanosine dose is not reduced, and this combination is not recommended as part of initial therapy. Dosing of didanosine should be reduced when co-administered with tenofovir. In adults, ARV regimens containing zidovudine may also impair rise in CD4 cell count but not CD4 percentage, perhaps through the myelosuppressive effects of zidovudine. Fortunately, this ARV drug-related suboptimal CD4 cell count response to therapy does not seem to confer an increased risk of clinical events. It is not clear whether this scenario warrants substitution of zidovudine with another drug.

Several drugs (e.g., corticosteroids, chemotherapeutic agents) and other conditions (e.g., hepatitis C, tuberculosis, malnutrition, Sjogren’s syndrome, sarcoidosis, syphilis) are independently associated with low CD4 values.

Poor Clinical Response Despite Adequate Virologic and Immunologic Responses

Clinicians must carefully evaluate patients who experience clinical disease progression despite favorable immunologic and virologic responses to cART. Not all cases represent cART failure. One of the most important reasons for new or recurrent opportunistic conditions despite achieving virologic suppression and immunologic restoration/preservation within the first months of cART is IRIS, which does not represent cART failure and does not generally require discontinuation of cART. Children who have suffered irreversible damage to their lungs, brain, or other organs—especially during prolonged and profound pretreatment immunosuppression—may continue to have recurrent infections or symptoms in the damaged organs because the immunologic improvement may not reverse damage to the organs. Such cases do not represent cART failure and, in these instances, children would not benefit from a change in ARV regimen. Before a definitive conclusion of cART clinical failure is reached, a child should also be evaluated to rule out (and, if indicated, treat) other causes or conditions that can occur with or without HIV-related immunosuppression, such as pulmonary tuberculosis, malnutrition, and malignancy. Occasionally, however, children will develop new HIV-related opportunistic conditions (e.g., Pneumocystis jirovecii pneumonia or esophageal candidiasis occurring more than 6 months after achieving markedly improved CD4 values and virologic suppression) not explained by IRIS, pre-existing organ damage, or another reason. Although such cases are rare, they may represent cART clinical failure and suggest that improvement in CD4 values may not necessarily represent normalization of immunologic function. In children who have signs of new or progressive abnormal neurodevelopment, some experts change the ARV regimen, aiming to include agents that are known to achieve higher concentrations in the central nervous system; however, the data supporting the strategy are mixed.22-26

**Management of Virologic Treatment Failure**

Since almost all ARV management decisions for treatment failure are based on addressing virologic failure, this section on managing treatment failure will address only virologic treatment failure (repeated plasma viral load >200 copies/mL after 6 months of therapy).

The approach to management and subsequent treatment of virologic treatment failure may differ depending on the etiology of the problem. Although the cause of virologic treatment failure may be multifactorial, it is generally the result of non-adherence. Assessment of a child with suspicion of virologic treatment failure should include evaluation of adherence to therapy, medication intolerance, pharmacokinetic (PK) explanations of low drug levels or elevated, potentially toxic levels, and evaluation of suspected drug resistance (see Antiretroviral Drug-Resistance Testing). The main barrier to long-term maintenance of sustained virologic suppression in adults and children is incomplete adherence to medication regimens, with subsequent emergence of viral mutations conferring partial or complete resistance to one or more of the components of the ARV regimen. Table 16 outlines a comprehensive approach to evaluating causes of virologic treatment failure in children, with particular attention to adherence.

</tbody>
</table>
Virologic Treatment Failure with No Viral Drug Resistance Identified

Persistent viremia in the absence of detectable viral resistance to current medications is usually a result of non-adherence, but it is important to exclude other factors such as poor drug absorption, incorrect dosing, and drug interactions. If adequate drug exposure can be ensured, then adherence to the current regimen should result in virologic suppression. Resistance testing should take place while a child is on therapy. After discontinuation of therapy, predominant plasma viral strains may quickly revert to wild-type and re-emerge as the predominant viral population, in which case resistance testing may fail to reveal drug-resistant virus (see Antiretroviral Drug-Resistance Testing). An approach to identifying resistance in this situation is to restart the prior medications while emphasizing adherence, and repeat resistance testing in 4 weeks if plasma virus remains detectable. If the HIV plasma viral load becomes undetectable, non-adherence was likely the original cause of virologic treatment failure.

Virologic failure of boosted protease inhibitor (PI)-based regimens (in the absence of prior treatment with full-dose ritonavir) is frequently associated with no detectable major PI resistance mutations, and virologic suppression may be achieved with continuation of the PI-based regimen accompanied by adherence improvement measures.27,28

In some cases, the availability of a new regimen for which the convenience (e.g., single fixed-dose tablet once daily) is anticipated to address the main barrier to adherence may make it reasonable to change to this new regimen with close adherence and viral load monitoring. In most cases, however, when there is evidence of poor adherence to the current regimen and an assessment that good adherence to a new regimen is unlikely, emphasis and effort should be placed on improving adherence before initiating a new regimen (see Adherence). When efforts to improve adherence will require several weeks or months, many clinicians may choose to continue the current non-suppressive regimen (see Management Options When Two Fully Active Agents Cannot Be Identified or Administered).29-31 Treatment with non-suppressive regimens in such situations should be regarded as an acceptable but not ideal interim strategy to prevent immunologic and clinical deterioration while working on adherence. Such patients should be followed more closely than those with stable virologic status, and the potential to successfully initiate a fully suppressive ARV drug regimen should be reassessed at every opportunity. Complete treatment interruption for a persistently non-adherent patient should prevent accumulation of additional drug resistance but has been associated with immunologic declines and poor clinical outcomes.32

Virologic Treatment Failure with Viral Drug Resistance Identified

After reaching a decision that a change in therapy is needed, a clinician should attempt to identify at least two, but preferably three, fully active ARV agents from at least two different classes on the basis of resistance test results, prior ARV exposure, acceptability to the patient, and likelihood of adherence.33-37 This often requires using agents from one or more drug classes that are new to the patient. Substitution or addition of a single drug to a failing regimen is not recommended because it is unlikely to lead to durable virologic suppression and will likely result in additional drug resistance. A drug may be new to the patient but have
diminished antiviral potency because of the presence of drug-resistance mutations that confer cross-resistance within a drug class.

A change to a new regimen must include an extensive discussion of treatment adherence and potential toxicity with a patient in an age- and development-appropriate manner and with a patient’s caregivers. Clinicians must recognize that conflicting requirements of some medications with respect to food and concomitant medication restrictions may complicate administration of a regimen. Timing of medication administration is particularly important to ensure adequate ARV drug exposures throughout the day. Palatability, size and number of pills, and dosing frequency all need to be considered when choosing a new regimen.38

**Therapeutic Options After Virologic Treatment Failure with Goal of Complete Virologic Suppression**

Determination of a new regimen with the best chance for complete virologic suppression in children who have already experienced treatment failure should be made by or in collaboration with a pediatric HIV specialist. ARV regimens should be chosen based on treatment history and drug-resistance testing to optimize ARV drug potency in the new regimen. A general strategy for regimen change is shown in Table 17, although as additional agents are licensed and studied for use in children, newer strategies that are better tailored to the needs of each patient may be constructed.

If a child has received initial therapy with an NNRTI-based regimen, a change to a PI-based regimen or integrase strand transfer inhibitor (INSTI)-based regimen is generally effective. Resistance to the NNRTI nevirapine results in cross-resistance to the NNRTI efavirenz, and vice versa. However, the NNRTI etravirine can retain activity against nevirapine- or efavirenz-resistant virus in the absence of certain key NNRTI mutations (see below), but etravirine has generally been tested only in regimens that also contain a boosted PI. If a child received initial therapy with a PI-based regimen, a change to an NNRTI-based regimen or an INSTI-based regimen is generally effective. Lopinavir/ritonavir-based regimens have also been shown to have durable ARV activity in some PI-experienced children.39-41

The availability of new drugs in existing classes (e.g., the NNRTI etravirine) and other classes of drugs (e.g., INSTI) increases the likelihood of finding three active drugs, even for children with extensive drug resistance (see Table 17). Etravirine in combination with darunavir/ritonavir has been shown to be a safe and effective option for children for whom first-line cART fails.42,43 Etravirine is approved for use in children aged ≥6 years and darunavir in children aged ≥3 years. Raltegravir, an INSTI, is approved for children aged ≥4 weeks.44 Dolutegravir is approved for use in adolescents aged ≥12 years. Use of newer agents in novel combinations is becoming more common in aging perinatally infected youth in the United States.45 It is important to review individual drug profiles for information about drug interactions and dose adjustment when devising a regimen for children with multi-class drug resistance. Appendix A: Pediatric Antiretroviral Drug Information provides more detailed information on drug formulation, pediatric and adult dosing, and toxicity, as well as discussion of available pediatric data for the approved ARV drugs.

Previously prescribed drugs that were discontinued because of poor tolerance or poor adherence may sometimes be reintroduced if ARV resistance did not develop and if prior difficulties with tolerance and adherence can be overcome (e.g., by switching from a liquid to a pill formulation or to a new formulation [e.g., ritonavir tablet]). Limited data in adults suggest that continuation of lamivudine can contribute to suppression of HIV replication despite the presence of lamivudine resistance mutations and can maintain lamivudine mutations (184V) that can partially reverse the effect of other mutations conferring resistance to zidovudine, stavudine, and tenofovir.46-48 The use of new drugs that have been evaluated in adults but have not been fully evaluated in children may be justified, and ideally would be done in the framework of a clinical trial. Expanded access programs or clinical trials may be available (see www.clinicaltrials.gov). New drugs should be used in combination with at least one, and ideally two, additional active agents.
Enfuvirtide has been Food and Drug Administration-approved for treatment-experienced children aged \( \geq 6 \) years but must be administered by subcutaneous injection twice daily.\(^{49,50}\) PK studies of certain dual-boosted PI regimens (lopinavir/ritonavir with saquinavir) suggest that PK targets for both PIs can be achieved or exceeded when used in combination in children.\(^{51-53}\) Multidrug regimens (up to 3 PIs and/or 2 NNRTIs) have shown efficacy in a pediatric case series, but they are complex, often poorly tolerated, and subject to unfavorable drug-drug interactions.\(^{54}\) Availability of newer PIs (e.g., darunavir) and new classes of ARV drugs (integrase and CCR5 inhibitors) have lessened the need for use of enfuvirtide, dual-PI regimens, and regimens of four or more drugs.

Studies of nucleoside reverse transcriptase inhibitor (NRTI)-sparing regimens in adults with virologic failure and multidrug resistance have demonstrated no clear benefit of including NRTIs in the new regimen,\(^{55,56}\) and one of these studies reported higher mortality in those adults randomized to a regimen with NRTIs compared to adults randomized to an NRTI-sparing regimen.\(^{56}\) There are no studies of NRTI-sparing regimens in children with virologic failure and multidrug resistance, but that may be a reasonable option for children with extensive NRTI resistance.

When searching for at least two fully active agents in cases of extensive drug resistance, clinicians should consider the potential availability and future use of newer therapeutic agents that may not be studied or approved in children or may be in clinical development. Information concerning potential clinical trials can be found at [http://aidsinfo.nih.gov/clinical_trials](http://aidsinfo.nih.gov/clinical_trials) and through collaboration with a pediatric HIV specialist. Children should be enrolled in clinical trials of new drugs whenever possible.

Pediatric dosing for off-label use of ARV drugs is problematic because absorption, hepatic metabolism, and excretion change with age.\(^{57}\) In clinical trials of several ARV agents, direct extrapolation of a pediatric dose from an adult dose, based on a child’s body weight or body surface area, was shown to result in an underestimation of the appropriate pediatric dose.\(^{58}\)

Use of ARV agents that do not have a pediatric indication (i.e., off-label) may be necessary for HIV-infected children with limited ARV options. In this circumstance, consultation with a pediatric HIV specialist for advice about potential regimens, assistance with access to unpublished data from clinical trials or other limited off-label pediatric use, and referral to suitable clinical trials is recommended.

**Management Options When Two Fully Active Agents Cannot Be Identified or Administered**

It may be impossible to provide an effective and sustainable therapeutic regimen because no combination of currently available agents is active against extensively drug-resistant virus in a patient or because a patient is unable to adhere to or tolerate cART.

The decision to continue a non-suppressive regimen must be made on an individual basis, weighing potential benefits and costs. Specifically, HIV providers must balance the inherent tension between the benefits of virologic suppression and the risks of continued viral replication and potential evolution of viral drug resistance in the setting of inadequate ARV drug exposure (i.e., non-adherence, non-suppressive suboptimal regimen). Non-suppressive regimens could decrease viral fitness and thus slow clinical and immunologic deterioration while a patient is either working on adherence or awaiting access to new agents that are expected to achieve sustained virologic suppression.\(^{59}\) However, persistent viremia in the context of ARV pressure has the potential to generate additional resistance mutations that could further compromise agents in the same class that might otherwise have been active in subsequent regimens (e.g., continuing first-generation INSTIs or NNRTIs). Patients continuing non-suppressive regimens should be followed more closely than those with stable virologic status, and the potential to successfully initiate a fully suppressive cART regimen should be reassessed at every opportunity.

The use of NRTI-only holding regimens or complete interruption of therapy is not recommended. In a trial (IMPAACT P1094) randomizing children harboring the M184V resistance mutation with persistent non-
adherence and virologic failure to continue their non-suppressive non-NNRTI-based cART regimen versus switching to a lamivudine (or emtricitabine) monotherapy holding regimen, children who switched to monotherapy experienced a 30% decline in absolute CD4 cell count (the primary outcome) over a 28-week period. The median age of the participants was 15 years and the median entry CD4 cell count was 472 cells/mm³, and the median number of interventions that had been used to address non-adherence was four. Only patients in the lamivudine/emtricitabine arm experienced the primary outcome.60 Although this was a small study (N = 33), it is the only study ever to randomize patients to continuing non-suppressive cART versus lamivudine/emtricitabine monotherapy, and it is unlikely that it will be repeated. Thus, NRTI-only holding regimens are not recommended as a treatment strategy for children failing non-suppressive cART. Complete treatment interruption has also been associated with immunologic declines and poor clinical outcomes and is not recommended.32 See Treatment Interruption.

a ARV regimens should be chosen based on treatment history and drug-resistance testing to optimize ARV drug effectiveness. This is particularly important in selecting NRTI components of an NNRTI-based regimen where drug resistance to the NRTIs can occur rapidly if the virus is not sufficiently sensitive to the NRTIs. Regimens should contain at least two, but preferably three, fully active drugs for durable, potent virologic suppression. Please see individual drug profiles for information about drug interactions and dose adjustment when devising a regimen for children with multi-class drug resistance. Collaboration with a pediatric HIV specialist is especially important when choosing regimens for children with multi-class drug resistance. Regimens in this table are provided as examples, but the list is not exhaustive.

b No current Food and Drug Administration-approved pediatric indication for maraviroc

Unplanned Interruptions

Temporary discontinuation of combination antiretroviral therapy (cART) may be indicated in some situations, including serious treatment-related toxicity, acute illnesses or planned surgeries that preclude oral intake, lack of available medication, or patient or parent request. Observational studies of children and youth with unplanned or non-prescribed treatment interruptions suggest that interruptions are common, most patients will experience immunologic decline during the treatment interruption, and most restart therapy.1-3

The case of an infant who initiated cART soon after birth and had a prolonged period without viremia after unplanned interruption is discussed in the Special Considerations for Neonates section.

Structured Treatment Interruptions

Planned periods during which antiretroviral therapy is not given, also known as “structured treatment interruptions,” were historically considered as a potential strategy to reduce toxicity, costs, and drug-related failure associated with cART.

Adult trials have demonstrated significantly higher morbidity and mortality in those randomized to structured treatment interruptions compared with continuous cART.4 Current Department of Health and Human Services guidelines for adults recommend against planned long-term structured treatment interruptions in adults (see the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents).

In children, there have been fewer studies of long-term structured treatment interruption. In one study, children with controlled viral load (HIV RNA <400 copies/mL for >12 months) were subjected to increasing intervals of treatment interruption. Of 14 children studied, 4 maintained undetectable viral loads with interruptions of up to 27 days. It has been hypothesized that enhanced HIV-specific immune responses may play a role in the viral suppression.5 However, new drug-resistance mutations were detected in 3 of 14 children in the structured treatment interruption study. In a European trial (PENTA 11), 109 children with virologic suppression on cART were randomized to continuous therapy (CT) versus treatment interruption with CD4 T lymphocyte (CD4)-guided re-initiation of cART.6 On average, CD4 values decreased sharply in the first 10 weeks after structured treatment interruption. However, most children in the structured treatment interruption arm (almost 60%) did not reach CD4 criteria to restart therapy over 48 weeks. Children in the structured treatment interruption arm spent significantly less time on cART than children in the CT arm. None of the children in the trial experienced serious clinical illnesses or events, and the appearance of new drug-resistance mutations did not differ between the two arms. In a recent analysis, every month of treatment interruption among children in the ARROW trial was associated with 2% (1% to 3%, P = 0.001) lower CD4 percentage by 3 years of follow up; having any interruption of treatment was associated with a trend to
increased mortality [hazard ratio: 2.6 (95% Confidence Interval 0.7–10.4)].

In some populations of children, structured treatment interruption has been more specifically considered. One trial was designed to answer whether infants who initiated cART early could safely discontinue therapy at some point and reinitiate treatment based on CD4 cell decline. The CHER study in South Africa assessed outcomes in infants randomized to deferred cART (initiation driven by CDC stage and CD4 status), immediate cART with interruption after 40 weeks, or immediate cART with interruption after 96 weeks. While the 2 arms of interrupted therapy led to better outcomes compared to the deferred arms, up to 80% of infants had to restart therapy by the end of follow-up. The long-term outcomes in children after this interruption remain unknown and it is unclear if the short period of time on cART saved by most children merits the potential risks associated with cessation.

Given the increased availability of medications with less toxicity, the potential benefits of long-term structured treatment interruption may be decreasing. Current data do not support use of long-term structured treatment interruption in clinical care of HIV-infected children; additional studies of structured treatment interruption in specific situations for some children may be warranted.

References

The goal of therapeutic drug monitoring (TDM) of antiretroviral (ARV) drugs is to optimize treatment responses and tolerability, and to minimize drug-associated toxicity. A number of adult studies suggest that modified doses and regimen choices based on TDM result in achievement of targeted ARV drug concentrations and are associated with improved clinical response and/or tolerability.1-7 In children, the usefulness of TDM to guide dosing of ARV drugs has been demonstrated in a number of non-randomized clinical trials and case reports.8-19

Dosing of ARV drugs in HIV-infected children and adolescents depends on chronological age and/or body parameters (e.g., height, weight). Ongoing growth requires continuous reassessment of dosing of ARV drugs in order to avoid low drug exposure and development of viral resistance and virologic failure. Developmental differences in drug absorption, distribution, metabolism, and elimination contribute to high variability and a greater frequency of suboptimal exposure to multiple therapeutic agents including ARVs in children and adolescents compared to adults.20,21 Suboptimal exposure to selected ARV agents with recommended dosing has been demonstrated in pediatric patients, especially in young children.14,15,23–25

Because of the diverse developmental challenges in palatability and acceptability of combination antiretroviral therapy (cART), children and adolescents are frequently faced with the use of altered dosing regimens and ARV combinations for which safety and efficacy have not been established in large clinical trials. Furthermore, dosing recommendations for ARV drugs at the time of licensing for pediatric use are frequently derived from a limited number of patients and pharmacokinetic (PK) modeling and may be revised as newer PK data become available.14,15,24 The Health and Human Services (HHS) Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel) recommends considering TDM for certain ARV agents when the newly approved pediatric formulation and/or dosing are used based on limited PK and efficacy data in small populations (see specific drug information sections).
TDM can also be considered in management of treatment failure for children on cART to increase efficacy and to decrease toxicity.

**Use of Therapeutic Drug Monitoring to Improve Efficacy**

The relationship between ARV drug concentrations and ARV efficacy must be clearly defined for TDM to be useful. This association has been shown to be the strongest for protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) as well as for the CCR5 receptor antagonist maraviroc. For nucleoside reverse transcriptase inhibitors (NRTIs), intracellular concentrations of their triphosphate metabolites have been shown to be most important in determining therapeutic response. Obtaining intracellular NRTI metabolite concentrations is expensive, labor-intensive, requires large blood volumes, and is limited to research settings. Limited data have demonstrated that serum concentrations of NRTIs are also correlated with virologic suppression; however, no efficacy plasma concentrations have been derived for NRTIs.

Based on data from adult studies, consensus target efficacy plasma trough concentrations for treatment-naive and treatment-experienced patients have been developed by clinical pharmacology experts from the United States and Europe for the many PIs and NNRTIs, as well as the CCR5 receptor antagonist maraviroc (see Table 18). Several of these targets (lopinavir, nelfinavir, efavirenz, nevirapine) have been validated in pediatric studies. Efficacy trough concentrations for maraviroc and tipranavir have been derived in patients with multiple drug-resistant HIV strains only. Although exposure-response data for the PI darunavir, the NNRTI etravirine, and the integrase inhibitor raltegravir are accumulating, they have been considered insufficient to define target efficacy concentrations at this time. Table 18 includes data on the plasma trough concentrations derived from clinical trials of these drugs.

\(^{e}\) Darunavir dose 600 mg twice daily  
\(^{f}\) Median (range)
The suggested efficacy plasma trough concentrations are generally applicable when the patient’s resistance testing demonstrates susceptibility to the particular ARV drug. In treatment-experienced patients with virologic failure, a higher plasma trough concentration may be required to suppress viral replication when there is decreased susceptibility to the ARV drug. Recent PK/pharmacodynamic modeling of lopinavir/ritonavir in children suggests that higher plasma exposure might be beneficial not only for treatment-experienced, but also for treatment-naive children, with the target plasma trough concentration of 2,400 ng/mL corresponding to C05 proposed as a target for increased efficacy. For the majority of PIs, viral resistance develops cumulatively with successive mutations, and higher drug exposure can potentially overcome lower levels of resistance. The concept of inhibitory quotient (IQ) has been developed and successfully applied to certain PIs. IQ is expressed as the ratio of patient plasma trough concentration (Cmin) to specific viral susceptibility parameters (e.g., fold change in inhibitory concentration or the number of drug-specific resistance-associated mutations). This approach does not apply to drugs with low, single mutation thresholds for resistance (e.g., the NNRTIs nevirapine and efavirenz) because it is not possible to overcome such resistance by increasing the ARV drug exposure. Suboptimal plasma concentrations of efavirenz and nevirapine have been linked to virologic failure in children. Evaluation of efavirenz plasma concentrations in combination with pharmacogenetic evaluation for the polymorphism of the main drug metabolizing enzyme cytochrome P (CYP) 450 CYP2B6 is recommended if efavirenz is used in children aged <3 years to avoid suboptimal drug exposure.

Use of Therapeutic Drug Monitoring to Decrease Toxicity

The exposure-toxicity response relationship has been well defined for the PIs indinavir and atazanavir and the NNRTI efavirenz. Increased plasma concentrations of atazanavir have been linked to elevated bilirubin concentrations in adolescents, and measurement of the atazanavir plasma concentrations has been suggested for management of the atazanavir-associated hyperbilirubinemia in adolescents.

Adverse central nervous system (CNS) effects (e.g., CNS depression, dizziness, insomnia, hallucinations) associated with efavirenz have been shown to correlate with efavirenz plasma trough concentrations >4 mcg/mL in adult and pediatric studies. TDM-guided reduction in the efavirenz dose has been shown to successfully reduce neuropsychiatric side effects while allowing for continued virologic suppression in prospective adult studies. Recent reports on the PK of efavirenz in children aged <3 years demonstrated a significant relationship between high plasma efavirenz median concentrations and area under the curve versus time concentration (AUC) and drug-associated hemolatric and CNS toxicity. Evaluation of the efavirenz plasma concentrations in combination with determination of polymorphism of the main drug-metabolizing enzyme CYP2B6 should be considered for preventing and decreasing efavirenz-associated adverse events in children aged <3 years and might be considered in older children (see next section on pharmacogenetics).

Pharmacogenetic Evaluation as Part of Therapeutic Drug Monitoring

The pharmacogenetics of HIV therapy investigate the interactions between human genetic polymorphisms and PK and the outcome of cART. Multiple metabolizing and drug transporter genes have been studied for their association with efficacy and toxicity of ARV drugs. The most clinically significant relationship is demonstrated by the association between the CYP2B6 G to T polymorphism and the PK, toxicity and clinical response to efavirenz. CYP2B6 T516T and G516T genotypes have been associated with elevated plasma efavirenz concentrations and CNS toxicity in children and adults, while CYP2B6 G516G genotype has been linked to low plasma concentrations of efavirenz, decreased rates of virologic suppression and development of resistance. Reducing the efavirenz dose in patients with the CYP2B6 T516T genotype has been shown to reverse or decrease drug-associated toxicity in adults and adolescents and to achieve therapeutic efavirenz concentrations. The effect of CYP2B6 G516T polymorphism on the PK of efavirenz appears to be most pronounced in younger children undergoing maturation of the CYP450 enzymatic system. In the ongoing PACTG P1070 study, efavirenz dosing of approximately 40 mg/kg in children aged <3 years produced therapeutic efavirenz plasma concentrations.
concerns in 68% of children with GG/GT 516 rapid CYP2B6 genotypes, while the same dose led to significantly higher exposure with treatment-related toxicities greater than grade 3 in children with TT 516CYP2B6 genotype. In this ongoing study, genotyping for CYP2B6 G516T polymorphism is incorporated in the pretreatment evaluation and will be used to determine the dosing regimen. While efavirenz is not recommended for initial therapy in children aged <3 years, should efavirenz use be considered in children aged <3 years, the Panel recommends obtaining CYP2B6 genotype as part of pretreatment evaluation and dose selection (see Efavirenz in Appendix A: Pediatric Antiretroviral Drug Information). For children aged >3 years with a known CYP2B6 poor metabolizer genotype, reduction of the recommended efavirenz dose may be considered. This dose reduction may prevent the risk or decrease the grade of CNS toxicity; however, it may also increase pill burden, particularly among adolescents who are using efavirenz-based fixed-dose combinations. If this approach is taken, subsequent TDM is recommended to ensure that the patient achieves recommended plasma trough therapeutic efavirenz concentrations.

Practical Considerations

The use of TDM in clinical practice poses multiple challenges, including availability of the ARV drug assays and certified laboratories; difficulties in collecting timed blood samples in children to obtain true plasma trough concentrations; prolonged time to obtain the results; limited availability of pharmacologic pediatric expertise; and cost and reimbursement considerations. More extended PK evaluation of the AUC in children involves higher volumes of blood samples, cost, and time commitment. Limited information on safety and effectiveness of dose adjustment strategies in children and adolescents may also limit the application of TDM in clinical practice.

When obtaining plasma concentrations in pediatric and adolescent patients, several important steps need to be taken. The accurate interpretation of TDM requires documentation of the following elements:

- Accurate information about the dose and formulation
- List of concomitant medications
- Food intake with the dose
- Timing of the dose and blood sample collection
- Adherence and resistance information

Additional practical suggestions on TDM of ARV drugs can be found in a position paper by the Adult AIDS Clinical Trials Group Pharmacology Committee and several pediatric review manuscripts. Most importantly, consultation with an expert in pediatric HIV pharmacology is required to obtain guidance on when to obtain samples for TDM, how to interpret the PK data, and how to evaluate the need for dose adjustment and repeat PK evaluation and follow up.

Antiretroviral Drug-Resistance Testing

Antiretroviral Drug-Resistance Testing (Last updated March 5, 2015; last reviewed March 5, 2015)

HIV replication is a continuous process in most untreated patients, leading to the daily production of billions of virions. The goal of combination antiretroviral therapy (cART) is to suppress HIV replication as rapidly and fully as possible, as indicated by a reduction in plasma HIV RNA to below the limit of detection using the most sensitive assays available. Unfortunately, mutations in HIV RNA arise during viral replication because HIV reverse transcriptase (RT) is a highly error-prone enzyme. Consequently, ongoing replication in the presence of antiretroviral (ARV) drugs, as occurs in suboptimal adherence, readily and progressively selects for strains of HIV with mutations that confer drug resistance. Viruses harboring resistance-associated mutations can be transmitted in both perinatal and non-perinatal infection, underscoring the importance of resistance testing at the time of HIV diagnosis before cART initiation.1,2

Drug-resistance detection methods vary depending on the class of ARV agents. Both genotypic assays and phenotypic assays currently are used to detect the presence of virus that is resistant to inhibitors of the HIV RT, integrase (IN), or protease (PR) enzymes. Clinical experience with testing for viral resistance to other agents is more limited, but genotypic assays that assess mutations in gp41 (envelope) genes also are commercially available. Experience is also limited with the use of commercially available genotypic and phenotypic assays in the evaluation of drug resistance in patients infected with non-B subtypes of HIV.3,4

Table 19 summarizes the indications for using available resistance testing.

Panel’s Recommendations

- Antiretroviral drug-resistance testing is recommended at the time of HIV diagnosis, before initiation of therapy, in all treatment-naïve patients (AII). Genotypic resistance testing is preferred for this purpose (AII).
- Antiretroviral drug resistance testing is recommended before changing therapy because of virologic failure (AII*).
- Resistance testing in patients with virological failure should be done while they are still on the failing regimen or within 4 weeks of discontinuation (AII*).
- Phenotypic resistance testing should be used (usually in addition to genotypic resistance testing) for patients with known or suspected complex drug resistance mutation patterns, which generally arise after virologic failure of successive antiretroviral therapy regimens (BIII).
- The absence of detectable resistance to a drug does not ensure that use of the drug will be successful as mutations may not be detected once the drug has been discontinued. A history of all previously used antiretroviral agents and available resistance test results must be reviewed when making decisions regarding the choice of new agents (AII).
- Viral coreceptor (tropism) assays should be used whenever the use of a CCR5 antagonist is being considered (AII*). Tropism assays should also be considered for patients who demonstrate virologic failure while receiving therapy that contains a CCR5 antagonist (AII*).
- Consultation with a pediatric HIV specialist is recommended for interpretation of resistance assays when considering starting or changing an antiretroviral regimen in pediatric patients (AII*).

Rating of Recommendations: A = Strong; B = Moderate; C = Optional

Rating of Evidence: I = One or more randomized trials in children† with clinical outcomes and/or validated endpoints; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory endpoints with accompanying data in children† from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children† with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children† from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = Expert opinion

† Studies that include children or children/adolescents, but not studies limited to post-pubertal adolescents

HIV Drug-Resistance and Resistance Assays

HIV replication is a continuous process in most untreated patients, leading to the daily production of billions of virions. The goal of combination antiretroviral therapy (cART) is to suppress HIV replication as rapidly and fully as possible, as indicated by a reduction in plasma HIV RNA to below the limit of detection using the most sensitive assays available. Unfortunately, mutations in HIV RNA arise during viral replication because HIV reverse transcriptase (RT) is a highly error-prone enzyme. Consequently, ongoing replication in the presence of antiretroviral (ARV) drugs, as occurs in suboptimal adherence, readily and progressively selects for strains of HIV with mutations that confer drug resistance. Viruses harboring resistance-associated mutations can be transmitted in both perinatal and non-perinatal infection, underscoring the importance of resistance testing at the time of HIV diagnosis before cART initiation.1,2

Drug-resistance detection methods vary depending on the class of ARV agents. Both genotypic assays and phenotypic assays currently are used to detect the presence of virus that is resistant to inhibitors of the HIV RT, integrase (IN), or protease (PR) enzymes. Clinical experience with testing for viral resistance to other agents is more limited, but genotypic assays that assess mutations in gp41 (envelope) genes also are commercially available. Experience is also limited with the use of commercially available genotypic and phenotypic assays in the evaluation of drug resistance in patients infected with non-B subtypes of HIV.3,4

Table 19 summarizes the indications for using available resistance testing.
**Genotypic Assays**

Genotypic assays for resistance to RT and PR inhibitors and IN strand transfer inhibitors are based on polymerase chain reaction amplification and analysis of the RT, PR, and IN coding sequences present in HIV RNA extracted from plasma. Genotypic assays can detect resistance mutations in plasma samples containing approximately 1,000 copies/mL or more of HIV RNA and results generally are available within 1 to 2 weeks of sample collection. Not all available genotypic tests include IN resistance; it may need to be specifically requested. Interpretation of test results requires knowledge of the mutations selected by different ARV drugs and of the potential for cross resistance to other drugs conferred by certain mutations. For some drugs, the genetic barrier to the development of resistance is low and a single nucleotide mutation is enough to confer high-level resistance sufficient to remove any clinical utility of the drug. This is exemplified by resistance to nevirapine and efavirenz resulting from mutations in the HIV RT (e.g., K103N). Other mutations lead to drug resistance but simultaneously impair HIV replication. Clinically useful activity of the ARV agent may therefore remain, as demonstrated by evidence of continued clinical benefit from lamivudine in individuals with evidence of the high-level lamivudine resistance engendered by the M184V RT mutation. By contrast, HIV evolution to high-level resistance to some drugs is associated with the emergence of mutations that confer resistance as well as compensatory mutations that allow the virus to replicate more efficiently in the presence of the ARV agent. In addition, polymorphisms that occur naturally or in the presence of drug and are not significant alone may confer clinically significant drug resistance when present with other polymorphisms or major resistance mutations.

The International AIDS Society-USA (IAS-USA) and the Stanford University HIV Drug Resistance Database maintain lists of resistance mutations that confer resistance to currently available ARV drugs (see [http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) or [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)). A variety of online tools analyze the simultaneous effect of all mutations detected in a patient in order to assist the provider in interpreting genotypic test results. Although the response to cART in children and adolescents is not always predicted by the results of genotypic resistance assays, clinical trials in adults have demonstrated the benefit of resistance testing combined with consultation with specialists in HIV drug resistance in improving virologic outcomes. Given the potential complexity of interpretation of genotypic resistance, it is recommended that clinicians consult with a pediatric HIV specialist for assistance in the interpretation of genotypic results and design of an optimal new regimen.

**Phenotypic Assays**

Phenotypic resistance assays provide a more direct assessment of the impact on ARV susceptibility of viral replication of mutations that are present in an individual’s HIV variants. As they are most often performed, phenotypic assays involve PCR amplification of the predominant RT, IN, PR, or gp41 envelope gene sequences from patient plasma and insertion of those amplified patient sequences into the backbone of a cloned strain of HIV that expresses a reporter gene. Replication of this recombinant virus in the presence of a range of drug concentrations is monitored by quantifying expression of the reporter gene and is compared with replication of a reference drug susceptible HIV variant. The drug concentration that inhibits viral replication by 50% (i.e., the mean inhibitory concentration [IC50]) is calculated, and the ratio of the IC50 of test and reference viruses is reported as the fold increase in IC50 (i.e., fold resistance change). Automated, recombinant phenotypic assays that can produce results in 2 to 3 weeks are commercially available; however, they are more costly than genotypic assays.

Analytic techniques have also been developed to use the genotype to predict the likelihood of a drug-resistant phenotype. This bioinformatic approach, currently applicable for RT, IN, and PR inhibitor resistance only, matches the pattern of mutations obtained from the patient sample with a large database of samples for which both genotype and phenotype are known. Therefore, the sample is assigned a predicted phenotype susceptibility (or virtual phenotype) based on the data from specimens matching the patient’s genotype.
**Tropism (Viral Coreceptor Usage) Assays**

HIV enters cells by a complex, multistep process that involves sequential interactions between the HIV envelope protein molecules and the CD4 T lymphocyte (CD4) receptor, and then with either the CCR5 or CXCR4 coreceptor molecules, culminating in the fusion of the viral and cellular membranes. Viruses initially are CCR5 tropic in the majority of untreated individuals, including infants and children perinatally infected with HIV. However, a shift in coreceptor tropism often occurs over time, from CCR5 usage to either CXCR4 or dual or mixed [D/M] tropism. Viral coreceptor (tropism) assays are used to detect virus with tropism that will (CCR5 tropism) or will not (CXCR4 tropism or D/M tropism) be blocked by CCR5 antagonists. Detection of viral variants with CXCR4 or D/M tropism indicates resistance to CCR5 antagonists. ARV-treated patients with extensive drug resistance are more likely to harbor detectable CXCR4- or D/M-tropic virus than untreated patients with comparable CD4 counts. Studies of heavily treated perinatally infected children and adolescents have shown CXCR4 tropism rates of 19% to 80%; however, most of the studies have used genotypic testing to determine tropism, which may be flawed, as discussed below.

Resistance to CCR5 antagonists is detected using specialized phenotypic assays (Phenoscript [VIRalliance] and Trofile™ [Monogram Biosciences, Inc.]). These assays involve the generation of recombinant viruses bearing patient-derived envelope proteins (gp120 and gp41). The relative capacity of these pseudoviruses to infect cells bearing the cell surface proteins CCR5 or CXCR4 is based on the expression of a reporter gene.

Detection of X4 or D/M tropism is a contraindication to the use of the CCR5 antagonists as part of a therapeutic regimen. Coreceptor assays must be performed before a CCR5 inhibitor is used and should be considered in patients exhibiting virologic failure on a CCR5 inhibitor such as maraviroc.

The Trofile™ assay takes about 2 weeks to perform and requires a plasma viral load ≥1000 copies/mL and at least 3 mL of plasma. The initial version of the Trofile™ assay used during the clinical trials that led to the licensure of maraviroc was able to detect X4-tropic virus with 100% sensitivity when present at a frequency of 10% of the plasma virus population, but only 83% sensitivity when the variant was present at a frequency of 5%. In initial clinical trials of CCR5 antagonist drugs, this sensitivity threshold was not always sufficient to exclude the presence of clinically meaningful levels of X4- or D/M-tropic virus in patients initiating a CCR5 inhibitor-based regimen. The current enhanced sensitivity version of the Trofile™ assay (Trofile-EST™) is able to detect X4- or D/M-tropic virus representing as little as 0.3% of the plasma virus. One of the tropism assays can also be performed following amplification of HIV sequences from peripheral blood DNA (Trofile-DNA™ [Monogram Biosciences, Inc.]) and may be most useful when a change to a regimen containing a CCR5 antagonist is being considered for individuals with plasma viral load below 1,000 copies/mL and can be used even when the viral load is undetectable (e.g., if single-drug substitution for toxicity).

**Limitations of Current Resistance and Tropism Assays**

Limitations of the genotypic, phenotypic, and phenotype-prediction assay approaches include lack of uniform quality assurance testing and high cost. In addition, drug-resistant variants are likely to exist at low levels in every HIV-infected patient. Drug-resistant viruses that constitute <10% to 20% of the circulating virus population or are present in the reservoir of latently infected cells may not be detected by any of the currently available commercial resistance assays. A comprehensive review of the past use of ARV agents and the virologic responses to those agents, and all prior resistance mutations (i.e., cumulative genotype), even if not present on the current genotype, is important in making decisions regarding the choice of new agents for patients with virologic failure.

The primary limitations of phenotypic assays are that their predictive power depends upon the sensitivity of the genotypic methods used and the number of matches to the patient’s genotype. These tests also are more costly than genotypic testing; therefore, their use should be reserved for clinical settings in which the information they provide will add benefit (see Table 19).

Genotypic assays to assess tropism have been proposed as an alternative approach to determining the tropism...
of plasma HIV. However, they are not currently recommended because the limited experience with this approach indicates that the sensitivity may be lower than phenotypic tropism assays, particularly in the setting of CCR5 antagonist interruption where reversion to wild-type may occur.\textsuperscript{22,23}

Although drug resistance may be detected in the circulating plasma of infants, children, and adults who are not receiving therapy at the time of the assay, loss of detectable resistance and reversion to predominantly wild-type virus often occur in the first 4 to 6 weeks after ARV drugs are stopped.\textsuperscript{24-26} As a result, resistance testing is of greatest value when performed prior to or within 4 weeks after drugs are discontinued, or as soon after diagnosis as possible.\textsuperscript{27} The absence of detectable resistance to a drug at the time of testing does not ensure that future use of the drug will be successful,\textsuperscript{1,28} especially if the agent shares cross resistance with drugs previously used. It may be prudent to repeat resistance testing if an incomplete virological response to a new treatment regimen is observed in an individual with prior treatment failure(s) (see Management of Children Receiving Antiretroviral Therapy).

**Use of Resistance Assays in Determining Initial Treatment**

Transmission of drug-resistant strains to newly infected individuals (via perinatal and non-perinatal transmission of HIV) has been well documented and is associated with suboptimal virologic response to initial cART if this resistance is not taken into account when designing the initial regimen.\textsuperscript{29-33} Drug-resistant variants of HIV may persist for months after birth in infected infants\textsuperscript{34} and impair the response to cART.\textsuperscript{35} Consequently, ARV drug-resistance testing is recommended for all treatment-naive children before therapy is initiated. Standard genotypic testing is preferred in this setting because it may reveal the presence of both RT and PR resistance mutations and polymorphisms that facilitate the replication of drug-resistant virus.

Genotypic testing for integrase resistance mutations prior to initial treatment is only recommended in special circumstances (e.g., acquisition of HIV from an individual treated with an integrase inhibitor with concern for transmission of integrase resistance).

**Use of Resistance Assays in the Event of Virologic Failure**

Several studies in adults\textsuperscript{5,8-14} have indicated that early virologic responses to salvage regimens were improved when results of resistance testing were available to guide changes in therapy, compared with responses observed when changes in therapy were guided only by clinical judgment. Although not yet confirmed in children,\textsuperscript{36} resistance testing appears to be a useful tool in selecting active drugs when changing ARV regimens in cases of virologic failure. Resistance testing also can help guide treatment decisions for patients with suboptimal viral load reduction because virologic failure in the setting of cART may be associated with resistance to only one component of the regimen.\textsuperscript{3} Poor adherence is the most common reason for virologic failure, regardless of whether resistance develops. It should always be suspected, confirmed, and addressed, especially when no evidence of resistance to a failing regimen is identified (see Management of Children Receiving Antiretroviral Therapy).

Conclusion (Last updated March 5, 2015; last reviewed March 5, 2015)

The care of HIV-infected children is complex and evolving rapidly as results of new research are reported, new antiretroviral (ARV) drugs are approved, and new approaches to treatment are recommended. Clinical trials to define appropriate drug dosing and toxicity in children ranging in age from infancy to adolescence are critical as new drugs become available. As additional ARV drugs become approved and optimal strategies for use of these drugs in children becomes better understood, the Panel will modify these guidelines. These guidelines are only a starting point for medical decision-making and are not meant to supersede the judgment of clinicians experienced in the care of HIV-infected children. Because of the complexity of caring for HIV-infected children, and the decreasing number of children with perinatally acquired HIV in the United States, health care providers with limited experience in the care of these patients should consult with a pediatric HIV specialist.

The Centers for Disease Control and Prevention, the National Institutes of Health, the HIV Medicine Association, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the American Academy of Pediatrics jointly developed and published guidelines for the prevention and treatment of opportunistic infections in HIV-exposed and HIV-infected children; these guidelines are available at http://aidsinfo.nih.gov.1 Similar guidelines for adults are also available at the same website.2

**Formulations**

**Pediatric Oral Solution:** 20 mg/mL

**Tablets:** 300 mg (scored)

**Fixed-Dose Combination Tablets:**

*With Lamivudine (3TC):*
  - ABC 600 mg + 3TC 300 mg (Epzicom)

*With Zidovudine (ZDV) and 3TC:*
  - ABC 300 mg + ZDV 300 mg + 3TC 150 mg (Trizivir)

*With 3TC and Dolutegravir:*
  - ABC 600 mg + 3TC 300 mg + Dolutegravir 50 mg (Triumeq)

**Generic Formulations:**

- ABC sulfate 300 mg tablets
- Fixed-dose combination tablets of ABC 300 mg + 3TC 150 mg + ZDV 300 mg

- In clinically stable patients with undetectable viral load and stable CD4 T lymphocyte cell counts for more than 24 weeks, changing from twice-daily to once-daily dosing at 16 to 20 mg/kg/day to a maximum of 600 mg once daily is recommended if part of a once-daily regimen (see text below).

**Selected Adverse Events**

- Hypersensitivity reactions (HSRs) can be fatal. HSRs usually occur during the first few weeks of starting therapy. Symptoms may include fever, rash, nausea, vomiting, malaise or fatigue, loss of appetite, and respiratory symptoms (e.g., cough and shortness of breath).

- Several observational cohort studies suggest increased risk of myocardial infarction in adults with recent or current use of abacavir; however, other studies have not substantiated this finding, and there are no data in children.

**Special Instructions**

- Test patients for the HLA-B*5701 allele before starting therapy to predict risk of HSR. Patients positive for the HLA-B*5701 allele should not be given abacavir. Patients with no prior HLA-B*5701 testing who are tolerating abacavir do not need to be tested.

- Warn patients and parents about risk of serious, potentially fatal HSR. Occurrence of HSRs requires immediate and permanent discontinuation of abacavir. Do not re-challenge.

- Abacavir can be given without regard to food. Oral solution does not require refrigeration.
Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- Abacavir does not inhibit, nor is it metabolized by, hepatic cytochrome P (CYP) 450 enzymes. Therefore, it does not cause changes in clearance of agents metabolized through these pathways, such as protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (see more information in Drug Interaction section below under Pediatric Use).
- Through interference with alcohol dehydrogenase and glucuronyl transferase, alcohol increases abacavir levels by 41%.

Major Toxicities

- More common: Nausea, vomiting, fever, headache, diarrhea, rash, and anorexia.
- Less common (more severe): Serious and sometimes fatal hypersensitivity reactions (HSRs) observed in approximately 5% of adults and children (rate varies by race/ethnicity) receiving abacavir. HSR to abacavir is a multi-organ clinical syndrome usually characterized by rash or signs or symptoms in two or more of the following groups:
  - Fever
  - Constitutional, including malaise, fatigue, or achiness
  - Gastrointestinal, including nausea, vomiting, diarrhea, or abdominal pain
  - Respiratory, including dyspnea, cough, or pharyngitis
  - Laboratory and radiologic abnormalities include elevated liver function tests, elevated creatine phosphokinase, elevated creatinine, lymphopenia, and pulmonary infiltrates. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have also been reported. Pancreatitis can occur. This reaction generally occurs in the first 6 weeks of therapy, but has also been reported after a single dose. If an HSR is suspected, abacavir should be stopped immediately and not restarted—hypotension and death may occur upon re-challenge. The risk of abacavir HSR is associated with the presence of HLA-B*5701 allele; it is greatly reduced by not using abacavir in those who test positive for the HLA-B*5701 allele.
- **Rare:** Increased liver enzymes, elevated blood glucose, elevated triglycerides, and possible increased risk of myocardial infarction (in observational studies in adults). Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Pancreatitis can occur.

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

**Pediatric Use**

**Approval**

Abacavir is Food and Drug Administration-approved for use in HIV-infected children as part of the nucleoside reverse transcriptase inhibitor (NRTI) component of antiretroviral therapy (ART).

**Efficacy**

Abacavir used either twice daily or once daily has demonstrated durable antiviral efficacy in pediatric clinical trials.\(^1\,^3\) A retrospective analysis of observational data from two cohorts of African children aged <16 years suggested lower levels of viral suppression in children receiving first-line abacavir/lamivudine-based ART compared to stavudine/lamivudine-based ART; however, observational data may have multiple confounders and further data collection and analysis are needed before conclusions can be drawn (see What to Start).\(^4\,^5\)

**Pharmacokinetics**

**Pharmacokinetics in Children**

Pharmacokinetic (PK) studies of abacavir in children aged <12 years have demonstrated that children have more rapid clearance of abacavir than adults and that pediatric doses approximately twice the directly scaled adult dose are necessary to achieve similar systemic exposure.\(^6\,^7\) Metabolic clearance of abacavir in adolescents and young adults (ages 13–25 years) is slower than that observed in younger children and approximates clearance seen in older adults.\(^8\)

**Exposure-Response Relationship**

Plasma area under the drug-concentration-by-time curve (AUC) correlates with virologic efficacy of abacavir, although the association is weak.\(^9\,^10\) Intracellular concentrations of NRTIs are most strongly associated with antiviral effectiveness, and the active form of abacavir is the intracellular metabolite carbovir triphosphate (CBV-TP).\(^11\,^12\) Measurement of intracellular CBV-TP is more difficult than measurement of plasma AUC, so the abacavir plasma AUC is frequently considered as a proxy measurement for intracellular concentrations. However, this relationship is not sufficiently strong that changes in plasma AUC can be assumed to reflect true changes in intracellular active drug.\(^13\) Intracellular CBV-TP concentrations are affected by gender and have been reported to be higher in females than in males.\(^13\,^15\) This effect of gender and the PIs (see Drug Interactions section below) on abacavir PK further complicates linkage of clinically available plasma abacavir concentrations with more difficult to obtain—but pharmacodynamically more important—intracellular CBV-TP concentrations.

**Drug Interactions**

Abacavir plasma AUC has been reported to be decreased by 17% and 32% with concurrent use of the PIs ritonavir-boosted atazanavir and ritonavir-boosted lopinavir, respectively.\(^16\) In a study comparing PK parameters of abacavir in combination with either ritonavir-boosted lopinavir or nevirapine, abacavir plasma AUC was decreased 40% by concurrent use of ritonavir-boosted lopinavir; however, the CBV-TP concentrations appeared to be increased in the ritonavir-boosted lopinavir cohort.\(^15\) When combined with darunavir/ritonavir, abacavir plasma AUC and trough concentrations were decreased by 27% and 38%, respectively; the CBV-TP AUC and trough concentrations were decreased by 12% and 32%, respectively.\(^17\) The mechanism and the clinical significance of these drug interactions with the PIs are unknown and need to be evaluated. No dose adjustments for abacavir or PIs are currently recommended.
**Dosing**

**Frequency of Administration**

Abacavir 600 mg is administered once daily in adults; however, once-daily use in children remains controversial. The PENTA-13 crossover trial compared abacavir exposure at 16 mg/kg once daily with 8 mg/kg twice daily in 24 children ages 2 to 13 years who had undetectable or low, stable viral loads. This study showed equivalent AUC\(_{0-24}\) for both dosing regimens and improved acceptability of therapy in the once-daily dosing arm.\(^{18,19}\) However, trough abacavir plasma concentrations were lower in younger children (ages 2–6 years) receiving the once-daily regimen.\(^{19}\) The PENTA-15 crossover trial studied 18 children ages 3 to 36 months, again comparing abacavir 16 mg/kg once daily versus 8 mg/kg twice daily in children with viral loads <400 copies/mL or with stable viral loads on twice-daily abacavir at baseline. Abacavir AUC\(_{0-24}\) and clearance were similar in children on the once- and twice-daily regimens. After the change from twice-daily to once-daily abacavir, viral load remained <400 copies/mL in 16 of 18 participants through 48 weeks of monitoring.\(^{20}\) A study of 41 children (aged 3 to 12 years) in Uganda who were stable on twice-daily fixed-dose coformulation of abacavir/lamivudine also showed equivalent AUC\(_{0-24}\) and stable clinical outcome (i.e., disease stage and CD4 T lymphocyte [CD4] cell count) after the switch to once-daily abacavir during a median follow-up of 1.15 years. Virologic outcome was not evaluated in this study.\(^{21}\)

---

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection
Most recently, a pediatric PK model was developed based on data from 69 children in the PENTA-13 and -15 trials and the ARROW study. Irrespective of age, body weight was identified as the most significant factor influencing the oral clearance of abacavir in children. Predicted steady state peak (C_{max}) and AUC_{0-12} abacavir concentrations on standard twice-daily dosing were lower in toddlers and infants aged 0.4 to 2.8 years when compared with children aged 3.6 to 12.8 years. Model-based predictions showed that equivalent systemic plasma abacavir exposure was achieved after once- or twice-daily dosing regimens. The model did not include information on ethnicity and other potentially important demographic factors. No clinical trials have been conducted involving children who initiated therapy with once-daily dosing of abacavir. None of the pediatric clinical trials evaluated the pharmacodynamically most important intracellular CBV-TP concentrations. All three pediatric studies presented in the table above enrolled only patients who had low viral loads or were clinically stable on twice-daily abacavir before changing to once-daily dosing. Recent data from 48-week follow-up in the ARROW trial demonstrated clinical noninferiority of once-daily (336 children) versus twice-daily abacavir (333 children) in combination with a once- or twice-daily lamivudine-based regimen. Therefore, as part of a once-daily regimen, the Panel suggests a switch from twice-daily to once-daily dosing of abacavir (at a dose of 16 to 20 mg/kg/dose [maximum of 600 mg] once daily) for clinically stable patients with undetectable viral loads and stable CD4 cell counts for more than 6 months.

**Toxicity**

Abacavir has less of an effect on mitochondrial function than zidovudine, stavudine, or didanosine.

**References**

Didanosine (ddl, Videx) *(Last updated March 5, 2015; last reviewed March 5, 2015)*

For additional information see Drugs@FDA: [http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm](http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm)

**Formulations**

Videx Pediatric Powder for Oral Solution: Reconstituted 10 mg/mL

Videx Enteric-Coated (EC) Delayed-Release Capsules (EC Beadlets): 125 mg, 200 mg, 250 mg, and 400 mg

Generic Didanosine Delayed-Release Capsules: 125 mg, 200 mg, 250 mg, and 400 mg

Tablet for Oral Suspension: 100 mg, 150 mg, and 200 mg

**Dosing Recommendations**

**Neonate/Infant Dose (Aged 2 Weeks to <3 Months):**
- 50 mg/m² of body surface area every 12 hours
- Manufacturer recommends 100 mg/m² of body surface area every 12 hours in this age range. The Panel members interpret pharmacokinetic data as suggesting potential increased toxicity at that dose in this age group and many would use 50 mg/m² body surface area every 12 hours.

**Infant Dose (Aged ≥3 Months to 8 Months):**
- 100 mg/m² body surface area every 12 hours

**Pediatric Dose of Oral Solution (Age >8 Months):**
- 120 mg/m² body surface area every 12 hours
- Dose range: 90–150 mg/m² body surface area every 12 hours. Do not exceed maximum adult dose; see table below.
- In treatment-naive children aged 3–21 years, 240 mg/m² body surface area once daily (oral solution or capsules) has effectively resulted in viral suppression.

**Pediatric Dose of Videx EC or Generic Capsules (Aged 6–18 Years and Body Weight ≥20 kg)**

**Selected Adverse Events**

- Peripheral neuropathy
- Electrolyte abnormalities
- Diarrhea, abdominal pain, nausea, and vomiting
- Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported (the risk is increased when didanosine is used in combination with stavudine).
- Pancreatitis (less common in children than in adults, more common in adults when didanosine is used in combination with tenofovir or stavudine)
- Non-cirrhotic portal hypertension
- Retinal changes, optic neuritis
- Insulin resistance/diabetes mellitus

**Special Instructions**

- Because food decreases absorption of didanosine, administration of didanosine on an empty stomach (30 minutes before or 2 hours after a meal) generally is recommended. To improve adherence, some practitioners administer didanosine without regard to timing of meals (see text below).
- Didanosine powder for oral solution and tablets for oral suspension contain antacids that may interfere with the absorption of other medications, including protease inhibitors (PIs). See individual PI for instructions on timing of administration. This interaction is
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Absorption:** The presence of antacids in didanosine oral solution and tablets for oral suspension has the potential to decrease the absorption of a number of medications if given at the same time. Many of these interactions can be avoided by timing doses to avoid giving other medications concurrently with didanosine oral solution.

- **Mechanism unknown:** Didanosine serum concentrations are increased when didanosine is co-administered with tenofovir disoproxil fumarate (tenofovir) and this combination should be avoided if possible.

- **Renal elimination:** Drugs that decrease renal function can decrease didanosine clearance.

- **Enhanced toxicity:** Didanosine mitochondrial toxicity is enhanced by ribavirin.

- **Overlapping toxicities:** The combination of stavudine with didanosine may result in enhanced toxicity. That combination should not generally be used (see below).

**Major Toxicities:**

- **More common:** Diarrhea, abdominal pain, nausea, and vomiting.

- **Less common (more severe):** Peripheral neuropathy, electrolyte abnormalities, and hyperuricemia. Lactic...
acidosis and hepatomegaly with steatosis, including fatal cases, have been reported, and are more common with didanosine in combination with stavudine. Pancreatitis (less common in children than in adults, more common when didanosine is used in combination with tenofovir or stavudine) can occur. Increased liver enzymes and retinal depigmentation and optic neuritis have been reported. \textbf{Fall in CD4 T lymphocyte count is reported with use of didanosine with tenofovir.}

- \textit{Rare}: Non-cirrhotic portal hypertension, presenting clinically with hematemesis, esophageal varices, ascites, and splenomegaly, and associated with increased transaminases, increased alkaline phosphatase, and thrombocytopenia, has been associated with long-term didanosine use.

\section*{Resistance}

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see \url{https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf}) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see \url{http://hivdb.stanford.edu/DR}).

\section*{Pediatric Use}

\subsection*{Approval}

Didanosine is Food and Drug Administration (FDA)-approved for use in children as part of a dual-nucleoside reverse transcriptase inhibitor backbone in combination antiretroviral therapy.

\subsection*{Dosing}

\textbf{Standard Dose in Children}

Recommended doses of didanosine oral solution in children have traditionally been 90 to 150 mg/m\textsuperscript{2} body surface area per dose twice daily. Doses higher than 180 mg/m\textsuperscript{2} body surface area twice daily are associated with increased toxicity.\textsuperscript{1} The pharmacokinetic (PK) variable of greatest pharmacodynamic significance is the area under the curve (AUC), with virologic response best with didanosine AUC $\geq$ 0.60 mg*h/L.\textsuperscript{2,3} In a simulation based on didanosine concentration data from 16 children, a dose of 90 mg/m\textsuperscript{2} body surface area twice daily was predicted to result in adequate drug exposure in only 57% of pediatric patients, compared with adequate exposure predicted in 88% of patients at a dose of 120 mg/m\textsuperscript{2} body surface area twice daily,\textsuperscript{3} so that is the currently recommended dose for children ages 8 months to 3 years.

\textbf{Special Considerations in Ages 2 Weeks to <3 Months}

For infants ages 2 weeks to 8 months, the FDA recommends 100 mg/m\textsuperscript{2} body surface area per dose twice daily, increasing to 120 mg/m\textsuperscript{2} body surface area per dose twice daily at age 8 months. However, 2 small studies suggest that a higher AUC is seen in infants aged <6 weeks and that a dose of 100 mg/m\textsuperscript{2} body surface area per day (either as 50 mg/m\textsuperscript{2} body surface area per dose twice daily or 100 mg/m\textsuperscript{2} body surface area once daily) in infants aged <6 weeks achieves AUCs consistent with those seen at higher doses when used in older children.\textsuperscript{4} Therefore, because these PK differences in younger infants (ages 2 weeks–3 months) compared with older children raise concern for increased toxicity in the younger age group, the Panel recommends a dose of 50 mg/m\textsuperscript{2} of body surface area twice daily for infants aged younger than 3 months.

\textbf{Frequency of Administration (Once-Daily or Twice-Daily)}

A once-daily dosing regimen may be preferable to promote adherence, and multiple studies support the favorable PKs and efficacy of once-daily dosing. In a study of 10 children aged 4 to 10 years, enteric-coated (EC) didanosine (Videx EC) administered as a single dose of 240 mg/m\textsuperscript{2} body surface area once daily was shown to have similar plasma AUC (although lower peak plasma concentrations) compared with the equivalent dose of buffered didanosine.\textsuperscript{5} The resultant intracellular (active) drug concentrations are unknown. In 24 HIV-infected children, didanosine oral solution at a dose of 180 mg/m\textsuperscript{2} body surface area once daily was compared with 90 mg/m\textsuperscript{2} body surface area twice daily, and the AUC was actually higher in the once-daily group than in the twice-daily group.\textsuperscript{6} Long-term virologic suppression with a once-daily regimen of
efavirenz, emtricitabine, and didanosine (oral solution or EC beadlet capsules) was reported in 37 treatment-naive children ages 3 to 21 years. The didanosine dose used in that study was 240 mg/m²/dose once daily, and PK analysis showed no dose changes were needed to reach PK targets. A European trial of once-daily combination therapy in 36 children ages 3 to 11 years that included didanosine at a dose of 200 to 240 mg/m² body surface area demonstrated safety and efficacy with up to 96 weeks of follow up. In 53 children with advanced symptomatic HIV infection, once- versus twice-daily didanosine at a dose of 270 mg/m² body surface area per day showed no difference in surrogate marker or clinical endpoints, except that weight gain was less in the children given once-daily therapy. In 51 children (median age 6.0 years, range 2.5 to 15.0 years) in Burkina Faso, the once-daily combination of didanosine-lamivudine-efavirenz resulted in Week-48 viral load <300 copies/mL in 81% of treated participants. That study used didanosine at a dose of 240 mg/m²/day, administered in the fasting state as tablets with a separate antacid (not EC capsules).

**Food Restrictions**

Although the prescribing information recommends taking didanosine on an empty stomach, this is impractical for infants who must be fed frequently and it may decrease medication adherence by increasing regimen complexity. A comparison showed that systemic exposure measured by AUC was similar whether didanosine oral solution was given to children with or without food; absorption of didanosine administered with food was slower and elimination more prolonged. To improve adherence, some practitioners administer didanosine without regard to timing of meals. Studies in adults suggest that didanosine can be given without regard to food. A European study dosed didanosine oral solution as part of a 4-drug regimen either 1 hour before or 1 hour after meals, but allowed the extended-release formulation to be given without food restriction and showed good virologic outcome with up to 96 weeks of follow-up.

### Formulations

**Pediatric Oral Solution**: 10 mg/mL  
**Caplets**: 200 mg  
**Generic Formulations**: none available  
**Fixed-Dose Combination Tablets**:
- With tenofovir disoproxil fumarate (tenofovir): 300 mg tenofovir plus 200 mg emtricitabine (Truvada)  
- With tenofovir and efavirenz: 300 mg tenofovir plus 200 mg emtricitabine plus 600 mg efavirenz (Atripla)  
- With tenofovir and rilpivirine: 300 mg tenofovir plus 200 mg emtricitabine plus 25 mg rilpivirine (Complera)  
- With emtricitabine and elvitegravir and cobicistat: 300 mg tenofovir plus 200 mg emtricitabine plus 150 mg elvitegravir plus 150 mg cobicistat (Striv Weber)

### Dosing Recommendations

**Neonate/Infant Dose (Aged 0 to <3 Months)**

**Oral Solution**:
- 3 mg/kg once daily.

**Pediatric Dose (Aged ≥3 Months to 17 Years)**

**Oral Solution**:
- 6 mg/kg (maximum dose 240 mg) once daily; higher maximum dose because the oral solution has 20% lower plasma exposure in pediatric pharmacokinetic analysis.

**Capsules (for Children who Weigh >33 kg)**:
- 200 mg once daily.

**Adolescent (Aged ≥18 Years)/Adult Dose**

**Oral Solution**:
- 240 mg (24 mL) once daily.

**Capsules**:
- 200 mg once daily.

**Fixed-Dose Combination Tablets**

**Truvada**

**Adolescent (Aged ≥12 Years and Weighing ≥35 kg) and Adult Dose**:
- 1 tablet once daily.

**Atripla**

**Adolescent (Aged ≥12 Years and Weighing ≥40 kg) and Adult Dose**:
- 1 tablet once daily.  
- **Administer without food.**

### Selected Adverse Events

- Minimal toxicity  
- Severe acute exacerbation of hepatitis can occur in hepatitis B virus (HBV)-coinfected patients who discontinue emtricitabine.  
- Hyperpigmentation/skin discoloration on palms and/or soles

### Special Instructions

- Although emtricitabine can be administered without regard to food, food requirements vary depending on the other ARVs contained in a combination tablet. For Atripla (administer without food) and Complera (administer with a meal of at least 400 calories), refer to efavirenz or rilpivirine special instructions.

- Emtricitabine oral solution can be kept at room temperature up to 77°F (25°C) if used within 3 months; refrigerate for longer-term storage.

- If using Striv Weber, please see the elvitegravir section of the drug appendix for additional information.

- Before using emtricitabine, screen patients for HBV.

### Metabolism

- **Limited metabolism**: No cytochrome P (CYP) 450 interactions.  
- **Renal excretion 86%**: Competition with other compounds that undergo renal elimination.  
- **Dosing of emtricitabine in patients with renal...**
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

• Other nucleoside reverse transcriptase inhibitors (NRTIs): Do not use emtricitabine in combination with lamivudine because the agents share similar resistance profiles and lack additive benefit. Do not use separately with Combivir, Epzicom, or Trizivir because lamivudine is a component of these combinations. Do not use separately when prescribing Truvada, Atripla, Complera, or Stribild because emtricitabine is a component of these formulations.

• Renal elimination: Competition with other compounds that undergo renal elimination (possible competition for renal tubular secretion). Drugs that decrease renal function could decrease clearance.

• Use with Stribild: If using Stribild, please see the elvitegravir section of the drug appendix for additional information.

Major Toxicities

• More common: Headache, insomnia, diarrhea, nausea, rash, and hyperpigmentation/skin discoloration (possibly more common in children).

• Less common (more severe): Neutropenia. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Exacerbations of hepatitis have occurred in HIV/hepatitis B virus (HBV)-coinfected patients who changed from emtricitabine-containing to non-emtricitabine-containing regimens.

Resistance

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

Pediatric Use

Approval

Emtricitabine is Food and Drug Administration (FDA)-approved for once-daily administration in children, starting at birth. Owing to its once-daily dosing, minimal toxicity, and pediatric pharmacokinetic (PK) data, emtricitabine is commonly used as part of a dual-NRTI backbone in combination antiretroviral therapy.
Efficacy and Pharmacokinetics

Pharmacokinetics

A single-dose PK study of emtricitabine liquid solution and capsules was performed in 25 HIV-infected children ages 2 to 17 years. Emtricitabine was found to be well absorbed following oral administration, with a mean elimination half-life of 11 hours (range 9.7 to 11.6 hours). Plasma concentrations in children receiving the 6 mg/kg emtricitabine once-daily dose were approximately equivalent to those in adults receiving the standard 200-mg dose.

A study in South Africa evaluated the PKs of emtricitabine in 20 HIV-exposed infants aged <3 months, given emtricitabine as 3 mg/kg once daily for two, 4-day courses, separated by an interval of ≥2 weeks. Emtricitabine exposure (area under the curve [AUC]) in neonates receiving 3 mg/kg emtricitabine once daily was in the range of pediatric patients aged >3 months receiving the recommended emtricitabine dose of 6 mg/kg once daily and adults receiving the once-daily recommended 200-mg emtricitabine dose (AUC approximately 10 hr*ug/mL). Over the first 3 months of life, emtricitabine AUC decreased with increasing age, correlating with an increase in total body clearance of the drug. In a small group of neonates (N = 6) receiving a single dose of emtricitabine 3 mg/kg after a single maternal dose of 600 mg during delivery, the AUC exceeded that seen in adults and older children, but the half-life (9.2 hours) was similar. Extensive safety data are lacking in this age range.

Efficacy

Based on the aforementioned dose-finding study, emtricitabine was studied at a dose of 6 mg/kg once daily in combination with other antiretroviral (ARV) drugs in 116 patients aged 3 months to 16 years. PK results were similar, and follow-up data extending to Week 96 indicated that 89% of the ARV-naive and 76% of the ARV-experienced children maintained suppression of plasma HIV RNA <400 copies/mL (75% of ARV-naive children and 67% of ARV-experienced children at <50 copies/mL). Minimal toxicity was observed in this trial. In PACTG P1021, emtricitabine at a dose of 6 mg/kg (maximum 240 mg/day as liquid or 200 mg/day as capsules) in combination with didanosine and efavirenz, all given once daily, was studied in 37 ARV-naive HIV-infected children ages 3 months to 21 years. Eighty-five percent of children achieved HIV RNA <400 copies/mL and 72% maintained HIV RNA suppression to <50 copies/mL through 96 weeks of therapy. The median CD4 T lymphocyte count rose by 329 cells/mm³ at Week 96.

Both emtricitabine and lamivudine have antiviral activity and efficacy against HBV. For a comprehensive review of this topic, hepatitis C, and tuberculosis during HIV coinfection, please see the Pediatric Opportunistic Infections Guidelines.

References

Lamivudine (3TC, Epivir)  (Last updated June 29, 2015; last reviewed June 29, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Oral Solution: 10 mg/mL (Epivir), 5 mg/mL (Epivir HBV*)
Tablets: 150 mg (scored) and 300 mg (Epivir); 100 mg (Epivir HBV*)
Generic Tablets: 100 mg, 150 mg, and 300 mg

Fixed-Dose Combination Tablets:

With zidovudine:
• 150 mg 3TC plus 300 mg zidovudine (Combivir)
With abacavir:
• 300 mg 3TC plus 600 mg abacavir (Epzicom)
With zidovudine and abacavir:
• 150 mg 3TC plus 300 mg zidovudine plus 300 mg abacavir (Trizivir)
With abacavir and dolutegravir:
• 300 mg 3TC plus 600 mg abacavir plus 50 mg dolutegravir (Triumeq)

Generic Fixed-Dose Combination Tablets:

With zidovudine:
• 150 mg 3TC plus 300 mg zidovudine
With zidovudine and abacavir:
• 150 mg 3TC plus 300 mg zidovudine plus 300 mg abacavir

* Epivir HBV oral solution and tablets contain a lower amount of 3TC than Epivir oral solution and tablets. The strength of 3TC in Epivir HBV solution and tablet was based on dosing for treatment of hepatitis B virus (HBV) infection (in people without HIV coinfection). If Epivir HBV is used in HIV-infected patients, the higher dosage indicated for HIV therapy should be used as part of an appropriate combination regimen. The Epivir HBV tablet is appropriate for use in children who require a 100-mg 3TC dose for treatment of HIV infection.

Dosing Recommendations

Neonate/Infant Dose (Aged <4 Weeks) for Prevention of Transmission or Treatment:
• 2 mg/kg twice daily

Pediatric Dose (Aged ≥4 Weeks):
• 4 mg/kg (up to 150 mg) twice daily

Pediatric Dosing for Scored 150-mg Tablet (Weight ≥14 kg)

Selected Adverse Events

• Minimal toxicity
• Exacerbation of hepatitis has been reported after discontinuation of 3TC in the setting of chronic HBV infection

Special Instructions

• 3TC can be given without regard to food.
• Store 3TC oral solution at room temperature.
• Screen patients for HBV infection before administering 3TC.

Metabolism

• Renal excretion; dosage adjustment required in renal insufficiency.
• Fixed-dose combination tablets should not be used in patients with creatinine clearance
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- Renal elimination: Drugs that decrease renal function could decrease clearance of lamivudine.
- Other nucleoside reverse transcriptase inhibitors: Do not use lamivudine in combination with emtricitabine because of the similar resistance profiles and no additive benefit. Do not use separately when prescribing Truvada, Atripla, Complera, or Stribild because emtricitabine is a component of these formulations. Do not use separately when prescribing Combivir, Epzicom, or Trizivir because lamivudine is already a component of these combinations.

Major Toxicities

- More common: Headache, nausea.
- Less common (more severe): Peripheral neuropathy, lipodystrophy/lipoatrophy.
- Rare: Increased liver enzymes. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported.

Resistance

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).
Pediatric Use

Approval
Lamivudine is Food and Drug Administration (FDA)-approved for treatment of children aged ≥3 months, and it is a common component of most nucleoside backbone regimens.

Efficacy
Lamivudine has been studied in HIV-infected children alone and in combination with other antiretroviral (ARV) drugs, and extensive data demonstrate that lamivudine appears safe and is associated with clinical improvement and virologic response, and it is commonly used in HIV-infected children as a component of a dual-nucleoside reverse transcriptase inhibitor (NRTI) backbone. In one study, the NRTI background components of lamivudine/abacavir were superior to zidovudine/lamivudine or zidovudine/abacavir in long-term virologic efficacy.

Pharmacokinetics in Infants
Because of its safety profile and availability in a liquid formulation, lamivudine has been given to infants during the first 6 weeks of life starting at a dose of 2 mg/kg every 12 hours before age 4 weeks. A population pharmacokinetic (PK) analysis of infants receiving lamivudine affirms that adjusting the dose of lamivudine from 2 mg/kg to 4 mg/kg every 12 hours at age 4 weeks for infants with normal maturation of renal function provides optimal lamivudine exposure. For infants in early life, the higher World Health Organization weight-band dosing (up to 5 times the FDA dose) results in increased plasma concentrations compared to the 2 mg/kg dosing. In HPTN 040, lamivudine was given for prophylaxis of perinatal transmission in the first 2 weeks of life along with nelfinavir and 6 weeks of zidovudine according to a weight band dosing scheme. All infants weighing >2,000 g received 6 mg twice daily and infants weighing ≤2000 g received 4 mg twice daily for 2 weeks. These doses resulted in lamivudine exposure similar to that seen in infants who received the standard 2 mg/kg/dose twice-daily dosing schedule for neonates.

Dosing Considerations—Once Daily versus Twice Daily Administration
The standard adult dosage for lamivudine is 300 mg once daily, but few data are available regarding once-daily administration of lamivudine in children. Population PK data indicate that once-daily dosing of 8 mg/kg leads to area under the curve (AUC)₀₋₂₄ values similar to 4 mg/kg twice daily but Cₘᵢₙ values significantly lower and Cₘₐₓ values significantly higher in children ages 1 to 18 years. Intensive PKs of once-daily versus twice-daily dosing of lamivudine were evaluated in HIV-infected children ages 2 to 13 years in the PENTA-13 trial, and in children 3 to 36 months of age in the PENTA 15 trial. Both trials were crossover design with doses of lamivudine of 8 mg/kg/once daily or 4 mg/kg/twice daily. AUC₀₋₂₄ and clearance values were similar and most children maintained an undetectable plasma RNA value after the switch. A study of 41 children ages 3 to 12 years (median age 7.6 years) in Uganda who were stable on twice-daily lamivudine also showed equivalent AUC₀₋₂₄ and good clinical outcome (disease stage and CD4 T lymphocyte [CD4] cell count) after a switch to once-daily lamivudine, with median follow-up of 1.15 years. All three studies enrolled only patients who had low viral load or were clinically stable on twice-daily lamivudine before changing to once-daily dosing. Nacro et al. studied a once-daily regimen in ARV-naive children in Burkina-Faso composed of non-enteric-coated (EC) didanosine, lamivudine, and efavirenz. Fifty-one children ranging in age from 30 months to 15 years were enrolled in this open-label, Phase II study lasting 12 months. The patients had advanced HIV infection with a mean CD4 percentage of 9 and median plasma RNA of 5.51 log₁₀ copies/mL. At 12-month follow-up, 50% of patients had a plasma RNA <50 copies/mL and 80% were <300 copies/mL with marked improvements in CD4 percentage. Twenty-two percent of patients harbored multi-class-resistant viral strains. While PK values were similar to the PENTA and ARROW trials, the study was complicated by use of non-EC didanosine, severe immunosuppression, and non-clade B virus. In addition, rates of virologic failure and resistance profiles were not separated by age. Therefore, the Panel supports consideration of switching to once-daily dosing of lamivudine from twice-daily dosing in clinically stable patients ages 3 years and older with a reasonable once-daily regimen, an undetectable viral load, and stable CD4 cell count, at a dose of 8 to 10 mg/kg/dose to a maximum of 300 mg once daily. More long-term clinical trials with viral efficacy endpoints are needed to confirm that once-daily dosing of lamivudine can be used effectively to initiate ARV therapy in children.
Lamivudine undergoes intracellular metabolism to its active form, lamivudine triphosphate. In adolescents, the mean half-life of intracellular lamivudine triphosphate (17.7 hours) is considerably longer than that of unphosphorylated lamivudine in plasma (1.5–2 hours). Intracellular concentrations of lamivudine triphosphate have been shown to be equivalent with once- and twice-daily dosing in adults and adolescents, supporting a recommendation for once-daily lamivudine dosing in adolescents ages 16 and older who weigh 50 kg or more.19,20

World Health Organization Dosing

Weight-band dosing recommendations for lamivudine have been developed for children weighing at least 14 kg and receiving the 150-mg scored tablets.21,22

Both emtricitabine and lamivudine have antiviral activity and efficacy against hepatitis B. For a comprehensive review of this topic, and hepatitis C and tuberculosis during HIV coinfection, the reader should access the Pediatric Opportunistic Infections guidelines.

</tr>
</tbody>
</table>

### Selected Adverse Events

- Mitochondrial toxicity
- Peripheral neuropathy
- Lipoatrophy
- Pancreatitis
- Lactic acidosis/severe hepatomegaly with hepatic steatosis (higher incidence than with other nucleoside reverse transcriptase inhibitors). The risk is increased when used in combination with didanosine.
- Hyperlipidemia
- Insulin resistance/diabetes mellitus
- Rapidly progressive ascending neuromuscular weakness (rare)

### Special Instructions

- Stavudine can be given without regard to food.
- Shake stavudine oral solution well before use. Keep refrigerated; the solution is stable for 30 days.

### Metabolism

- Renal excretion 50%. Decrease dose in renal dysfunction.
- Stavudine is phosphorylated intracellularly to the active metabolite stavudine triphosphate.

### Drug Interactions

- **Renal elimination:** Drugs that decrease renal function could decrease stavudine clearance.
- **Other nucleoside reverse transcriptase inhibitors (NRTIs):** Stavudine should not be administered in combination with zidovudine because of virologic antagonism.

---

**Stavudine (d4T, Zerit) (Last updated March 5, 2015; last reviewed March 5, 2015)**

For additional information see Drugs@FDA: [http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm](http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm)

**Formulations**

- **Powder for Oral Solution:** 1 mg/mL
- **Capsules:** 15 mg, 20 mg, 30 mg, and 40 mg

**Generic Formulations:** Stavudine capsules and solution have been approved by the Food and Drug Administration for manufacture and distribution in the United States.
• **Overlapping toxicities:** The combination of stavudine and didanosine is not recommended because of overlapping toxicities. Reported toxicities are more often reported in adults and include serious, even fatal, cases of lactic acidosis with hepatic steatosis with or without pancreatitis in pregnant women.

• **Ribavirin and interferon:** Hepatic decompensation (sometimes fatal) has occurred in HIV/hepatitis C virus-coinfected patients receiving combination antiretroviral therapy (cART), interferon, and ribavirin.

• **Doxorubicin:** Simultaneous use of doxorubicin and stavudine should be avoided. Doxorubicin may inhibit the phosphorylation of stavudine to its active form.

**Major Toxicities**

• **More common:** Headache, gastrointestinal disturbances, skin rashes, hyperlipidemia, and fat maldistribution.

• **Less common (more severe):** Peripheral sensory neuropathy is dose-related and occurs more frequently in patients with advanced HIV disease, a history of peripheral neuropathy, and in those patients receiving other drugs associated with neuropathy. Pancreatitis. Lactic acidosis and severe hepatomegaly with hepatic steatosis, including fatal cases, have been reported. The combination of stavudine with didanosine may result in enhanced toxicity (increased risk of fatal and nonfatal cases of lactic acidosis, pancreatitis, peripheral neuropathy, and hepatotoxicity), particularly in adults, including pregnant women. This combination should not be used for initial therapy. Risk factors found to be associated with lactic acidosis in adults include female gender, obesity, and prolonged nucleoside exposure.¹

• **Rare:** Increased liver enzymes and hepatic toxicity, which may be severe or fatal. Neurologic symptoms including rapidly progressive ascending neuromuscular weakness are most often seen in the setting of lactic acidosis.

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)), and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

**Pediatric Use**

**Approval**

Although stavudine is Food and Drug Administration (FDA)-approved for use in children, its use is limited because it carries a higher risk of side effects associated with mitochondrial toxicity and a higher incidence of lipoatrophy than other NRTIs.

**Efficacy**

Data from multiple pediatric studies of stavudine alone or in combination with other antiretroviral (ARV) agents demonstrate that stavudine appears safe and is associated with clinical and virologic response.²⁻⁸ In resource-limited countries, stavudine is frequently a component of initial cART with lamivudine and nevirapine in children, often as a component of fixed-dose combinations not available in the United States. In this setting, reported outcomes from observational studies are good; data show substantial increases in the CD4 T lymphocyte (CD4) count and complete viral suppression in 50% to 80% of treatment-naive children.⁹⁻¹² In such a setting, where pediatric patients are already predisposed to anemia because of malnutrition, parasitic infestations, or sickle cell anemia, stavudine carries a lower risk of hematologic toxicity than zidovudine, especially in patients receiving cotrimoxazole prophylaxis.¹³ Short-term use of stavudine in certain settings where access to other ARVs may be limited remains an important strategy for treatment of children.¹⁴¹⁵
**Toxicity**

Stavudine is associated with a higher rate of adverse events than zidovudine in adults and children receiving cART. In a large pediatric natural history study (PACTG 219C), stavudine-containing regimens had a modest—but significantly higher—rate of clinical and laboratory toxicities than those containing zidovudine, with pancreatitis, peripheral neuropathy, and lipodystrophy/lipoatrophy (fat maldistribution) associated more often with stavudine use. Peripheral neuropathy is an important toxicity associated with stavudine but appears to be less common in children than in adults. In Pediatric AIDS Clinical Trials Group (PACTG) 219C, peripheral neuropathy was recognized in 0.9% of children.

**Lipodystrophy and Metabolic Abnormalities**

Lipodystrophy syndrome (LS), and specifically lipoatrophy (loss of subcutaneous fat), are toxicities associated with NRTIs, particularly stavudine, in adults and children. Children with metabolic disorders and abnormalities in body fat distribution, including fat loss and central fat accumulation may potentially be at increased risk of cardiovascular disease in early adulthood. Stavudine use has consistently been associated with a higher risk of lipodystrophy and other metabolic abnormalities (e.g., insulin resistance) in multiple pediatric studies involving children from the United States, Europe, Tanzania, Uganda, and Thailand. Lipodystrophy developed in 27% to 66% of children, with lipoatrophy being the most common form of lipodystrophy. The wide range of reported rates of LS is influenced by lack of consensus about clinical definition, ability of clinical staff to identify fat abnormalities in children, measurements used to diagnose abnormalities, duration of follow-up, and population differences. Evaluation of LS in Tanzanian children found that anthropometric measurements predicted LS in well-nourished children, but generally failed to do so in children with lower weights. While ever- or current-stavudine use has consistently been associated with a higher risk of LS, additional factors include older age and duration on ARVs. Improvements in lipodystrophy have been observed among Thai children after discontinuation of stavudine in two separate studies. Improvement or resolution was reported in 22.9% to 73% of cases.

Lactic acidosis with hepatic steatosis, including fatal cases, has been reported with use of nucleoside analogues, including stavudine, alone or in combination with didanosine. In adults, female gender, higher body mass index (BMI), and lower initial CD4 cell count are risk factors for developing lactic acidosis and hyperlactatemia. The combination of stavudine and didanosine in pregnant women has been associated with fatal lactic acidosis and should be used during pregnancy only if no other alternatives are available (for additional information on lactic acidosis see Table 13g in Management of Medication Toxicity or Intolerance).

**Mechanism**

Many of the above-mentioned adverse events are believed to be due to mitochondrial toxicity resulting from inhibition of mitochondrial DNA polymerase gamma, with depletion of mitochondrial DNA in fat, muscle, peripheral blood mononuclear cells, and other tissues. In a recent analysis involving a large cohort of pediatric patients (PACTG protocols 219 and 219C), possible mitochondrial dysfunction was associated with NRTI use, especially in children receiving stavudine and/or lamivudine.

**World Health Organization Recommendations**

The World Health Organization (WHO) strongly recommends that a maximum stavudine dose of 30 mg twice daily be used instead of the FDA-recommended 40 mg twice daily in patients weighing 60 kg or more. Several studies have compared the efficacy and toxicity of the two doses. The 30-mg dose is associated with similar efficacy but significantly lower incidence of peripheral neuropathy than the 40-mg dose. However, the overall incidence of toxicity was considered to be unacceptably high. Lipoatrophy and peripheral neuropathy are more likely to occur with higher doses but the risk of lactic acidosis is associated with female gender and a high BMI. When data from 48,785 adult patients from 23 HIV programs in resource-limited countries were evaluated, factors associated with higher toxicity rates included stavudine 40-mg dose, female gender, older age, advanced clinical stage, and low CD4 counts at the time of...
initiation of therapy.\textsuperscript{43} A recent South African study involving 3,910 adult patients on stavudine, confirmed higher rates of drug-related toxicity for peripheral neuropathy (OR 3.12), lipoatrophy (OR 11.8), and hyperlactatemia/lactic acidosis (OR 8.37) in patients receiving the 40-mg dose compared to the 30-mg dose. Patients receiving the higher dose also were more likely to discontinue stavudine use (OR 1.71) during the first year on cART.\textsuperscript{44} Continued prospective analysis of this cohort has confirmed that treatment initiation with tenofovir disoproxil fumarate has lowered drug-related adverse effects and that stavudine use is declining in South Africa.\textsuperscript{45} WHO recommends that stavudine be phased out of use because of concerns about unacceptable toxicity, even at the lower dose, since safer alternative agents may be prescribed.

**Pharmacokinetics**

Current pediatric dosing recommendations are based on early pharmacokinetic (PK) studies designed to achieve exposure (area under the curve) in children similar to that found in adults receiving a dose with proven efficacy.\textsuperscript{46} These early studies were conducted at a time when treatment options were limited and many children had failure to thrive. The authors in this early PK study state that stavudine distributes in total body water and, because total body weight correlates well with lean body mass (or weight), stavudine dosages in obese children should be based on lean body weight.\textsuperscript{46}

Although WHO has recommended a reduced dose in adults, a similar dose reduction has not been suggested in children. A reduced pediatric dose has been proposed based on PK modeling, but clinical data on intracellular concentrations of the active stavudine triphosphate are lacking.\textsuperscript{47}

**Formulations**

The pediatric formulation for stavudine oral solution requires refrigeration and has limited stability once reconstituted. As an alternative dosing method for children, capsules can be opened and dispersed in a small amount of water, with the appropriate dose drawn up into an oral syringe and administered immediately. Because plasma exposure is equivalent with stavudine administered in an intact or a dispersed capsule, dosing with the dispersal method can be used as an alternative to the oral solution.\textsuperscript{48}

Tenofovir Disoproxil Fumarate (TDF, Viread)  (Last updated April 27, 2015; last reviewed April 27, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Oral Powder: 40 mg per 1 g of oral powder (1 level scoop = 1 g oral powder; supplied with dosing scoop)

Tablets: 150 mg, 200 mg, 250 mg, and 300 mg

Fixed-Dose Combination Tablets:

With emtricitabine:
• 200 mg emtricitabine plus 300 mg tenofovir disoproxil fumarate (hereafter, TDF) (Truvada)

With emtricitabine plus efavirenz:
• 200 mg emtricitabine plus 600 mg efavirenz plus 300 mg TDF (Atripla)

With emtricitabine plus rilpivirine:
• 200 mg emtricitabine plus 25 mg rilpivirine plus 300 mg TDF (Complera)

With emtricitabine plus elvitegravir plus cobicistat:
• 200 mg emtricitabine plus 150 mg elvitegravir plus 150 mg cobicistat plus 300 mg TDF (Stribild)

Dosing Recommendations

Neonate/Infant Dose:
• Not Food and Drug Administration (FDA)-approved or recommended for use in neonates/infants aged <2 years.

Pediatric Dose (Aged ≥2 Years to <12 Years):
• 8 mg/kg/dose once daily

Selected Adverse Events

• Asthenia, headache, diarrhea, nausea, vomiting, flatulence
• Renal insufficiency, proximal renal tubular dysfunction that may include Fanconi syndrome
• Decreased bone mineral density (BMD)

Special Instructions

• Do not crush tablets; Oral powder formulation is available for patients unable to swallow tablets.
• Oral powder should be measured only with the supplied dosing scoop: 1 level scoop = 1 g powder = 40 mg TDF.
• Mix oral powder in 2 to 4 oz of soft food that does not require chewing (e.g., applesauce, yogurt). Administer immediately after mixing to avoid the bitter taste.
• Do not try to mix the oral powder with liquid: The powder may float on the top even after vigorous stirring.
• Although TDF can be administered without regard to food, food requirements vary depending on the other ARVs contained in a

Adolescent (Aged ≥12 Years and Weight ≥35 kg)* and Adult Dose:
- 300 mg once daily

Fixed-Dose Combination Tablets

*Truvada (TDF plus emtricitabine):*
- Adolescent (aged ≥12 years and weight ≥35 kg) and adult dose: 1 tablet once daily.

*Atripla (TDF plus emtricitabine plus efavirenz):*
- Adolescent (aged ≥12 years and weight ≥40 kg) and adult dose: 1 tablet once daily.

*Complera (TDF plus emtricitabine plus rilpivirine):*
- Adult dose (aged ≥18 years): 1 tablet once daily in treatment-naive adults with baseline viral load <100,000 copies/mL or virologically suppressed adults, with no history of virologic failure, resistance to rilpivirine and other ARVs, and who are currently on their first or second regimen.
  - Administer with a meal of at least 400 calories.

*Stribild (TDF plus emtricitabine plus elvitegravir plus cobicistat):*
- Adult dose (aged ≥18 years): 1 tablet once daily in treatment-naive adults. Administer with food.

Combinations with Other ARVs

*TDF in combination with didanosine:*
- Co-administration increases didanosine concentrations, so the combination of TDF and didanosine should be avoided if possible. If used, requires didanosine dose reduction (see section on didanosine).

*TDF in combination with atazanavir:*
- Co-administration reduces atazanavir concentrations, so when atazanavir is used in combination with TDF, atazanavir should always be boosted with ritonavir. Atazanavir co-administration increases TDF concentrations, so monitor for TDF toxicity.

*TDF in combination with lopinavir/ritonavir*
- Co-administration increases TDF concentrations. Monitor for TDF toxicity.

• Measure serum creatinine and urine dipstick for protein and glucose before starting a TDF-containing regimen and monitor serum creatinine and urine dipstick for protein and glucose at intervals (see Table 13) during continued therapy. Measure serum phosphate if clinical suspicion of hypophosphatemia.

• Screen patients for hepatitis B virus (HBV) infection before use of TDF. Severe acute exacerbation of HBV infection can occur when TDF is discontinued; therefore, monitor hepatic function for several months after therapy with TDF is stopped.

• If using Stribild, please see the elvitegravir section of the drug appendix for additional information.

Metabolism

• Renal excretion.

• Dosing of TDF in patients with renal insufficiency: Decreased dosage should be used in patients with impaired renal function (creatinine clearance <50 mL/min). Consult manufacturer’s prescribing information for adjustment of dosage in accordance with creatinine clearance (CrCl).

*Atripla and Complera (fixed-dose combinations) should not be used in patients with CrCl <50 mL/min or in patients requiring dialysis.

*Truvada (fixed-dose combination) should not be used in patients with CrCl <30 mL/min or in patients requiring dialysis.

*Stribild should not be initiated in patients with estimated CrCl <70 mL/min and should be discontinued in patients with estimated CrCl <50 mL/min.

*Stribild should not be used in patients with severe hepatic impairment.

* See text for concerns about decreased BMD, especially in prepubertal patients and those in early puberty (Tanner Stages 1 and 2).

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection P-30
**Drug Interactions** (see also the [Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents](#) and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- **Renal elimination**: Drugs that decrease renal function or compete for active tubular secretion could reduce clearance of tenofovir.

- **Other nucleoside reverse transcriptase inhibitors (NRTIs)**: Didanosine serum concentrations are increased when the drug is co-administered with tenofovir and this combination should be avoided if possible because of increase in didanosine toxicity.

- **Protease inhibitors (PIs)**: TDF decreases atazanavir plasma concentrations. Atazanavir without ritonavir should not be co-administered with TDF. In addition, atazanavir and lopinavir/ritonavir increase tenofovir concentrations and could potentiate TDF-associated toxicity.

- **Use of Stribild**: If using Stribild, please see the elvitegravir section of the drug appendix for additional information.

**Major Toxicities**

- **More common**: Nausea, diarrhea, vomiting, and flatulence.

- **Less common (more severe)**: TDF caused bone toxicity (osteomalacia and reduced bone density) in animals when given in high doses. Decreases in bone mineral density (BMD) have been reported in both adults and children taking TDF; the clinical significance of these changes is not yet known. Renal toxicity, including increased serum creatinine, glycosuria, proteinuria, phosphaturia, and/or calciuria and decreases in serum phosphate, has been observed. Patients at increased risk of renal glomerular or tubular dysfunction should be closely monitored. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported.

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

**Pediatric Use**

**Approval**

TDF is Food and Drug Administration (FDA)-approved for use in children aged ≥2 years when used as a component of the two-NRTI backbone in combination antiretroviral therapy (cART).

TDF has antiviral activity and efficacy against hepatitis B virus (HBV). For a comprehensive review of this topic, and Hepatitis C and tuberculosis during HIV coinfection, please see the [Pediatric Opportunistic Infections guidelines](#). Testing for HBV should be performed prior to starting TDF treatment.

**Efficacy in Clinical Trials in Adults Compared to Children and Adolescents**

The standard adult dose of TDF approved by the FDA for adults and children aged ≥12 years and weight ≥35 kg is 300 mg once daily; for children ages 2 to 12 years, the FDA-approved dose is 8 mg/kg/dose administered once daily, which closely approximates the dose of 208 mg/m²/dose used in early studies in children.⁴

In adults, the recommended dose is highly effective. ² ³

In children aged 12 to <18 years, no difference in viral load response was seen between two groups in a randomized, placebo-controlled trial of TDF 300 mg once daily or placebo, plus an optimized background regimen, in 87 treatment-experienced adolescents in Brazil and Panama⁴ Subgroup analyses suggest this lack of response was from imbalances in viral susceptibility to the optimized background regimens.
In children ages 2 to <12 years, TDF 8 mg/kg/dose once daily showed non-inferiority to twice daily zidovudine- or stavudine-containing cART over 48 weeks of randomized treatment using a snapshot analysis.5

Other pediatric studies also suggest that virologic success is related to prior treatment experience. In 115 pediatric patients treated with TDF, viral load decreased to <50 copies/mL at 12 months in 50%, 39%, and 13% of patients on first-, second-, and third-line therapy, respectively.6 This cohort used a target dose of 8 mg/kg, but 18% of patients were dosed at greater than 120% of the target dose and 37% were dosed at less than 80% of the target dose.

Pharmacokinetics

Relationship of Drug Exposure to Virologic Response and Toxicity

Virologic success is related to drug exposure. In a study using a median daily dose of 208 mg/m²,7 lower area under the curve (AUC) plasma tenofovir concentrations were associated with inferior virologic outcome.

Pharmacokinetic (PK) studies in children receiving an investigational 75-mg tablet formulation of TDF showed that a median dose of 208 mg/m² of body surface area (range 161–256 mg/m² body surface area) resulted in a median single dose AUC and maximum plasma concentration (C_max) that were 34% and 27% lower, respectively, compared with values reported in adults administered a daily dose of 300 mg.1,8 Renal clearance of tenofovir was approximately 1.5-fold higher in children than previously reported in adults, possibly explaining the lower systemic exposure.1 This lower exposure occurred even though participants were concurrently treated with ritonavir, which boosts tenofovir exposure. Lower-than-anticipated tenofovir exposure was also found in young adults (median age 23 years) treated with ritonavir-boosted atazanavir plus TDF,9 although PK modeling suggested a higher intracellular tenofovir diphosphate concentration in younger patients.10

Formulations

Special Considerations

The taste-masked granules that make up the oral powder give the vehicle (e.g., applesauce, yogurt) a gritty consistency. Once mixed in the vehicle, TDF should be administered promptly because, if allowed to sit too long, its taste becomes bitter.

Toxicity

Bone

Decreased bone mineral density (BMD) has been reported in both adult and pediatric studies. Younger children (i.e., Tanner Stages 1 and 2) may be at higher risk than children with more advanced development (i.e., Tanner Stage ≥3).1,11,12 In a Phase I/II study of an investigational 75-mg formulation of TDF in 18 heavily pretreated children and adolescents, a >6% decrease in BMD measured by dual-energy x-ray absorptiometry (DXA) scan was reported in 5 of 15 (33%) children evaluated at Week 48.1 Two of the 5 children who discontinued TDF at 48 weeks experienced partial or complete recovery of BMD by 96 weeks.13 Among children with BMD decreases, the median Tanner score was 1 (range 1–3) and mean age was 10.2 years; for children who had no BMD decreases, the median Tanner score was 2.5 (range 1–4) and median age was 13.2 years.7,13 In a second study of 6 patients who received the commercially available, 300 mg formulation of TDF, 2 prepubertal children experienced >6% BMD decreases. One of the 2 children experienced a 27% decrease in BMD, necessitating withdrawal of TDF from her cART regimen with subsequent recovery of BMD.14 Loss of BMD at 48 weeks was associated with higher drug exposure.7

In the industry-sponsored study that led to FDA approval of TDF in adolescents aged ≥12 years and weight ≥35 kg, 6 of 33 participants (18%) in the TDF arm experienced a >4% decline in absolute lumbar spine BMD in 48 weeks compared with 1 of 33 participants (3%) in the placebo arm.4

In the Gilead switch study in children ages 2 to 12 years over the 48 weeks of randomized treatment, total
body BMD gain was less in the TDF group than in the zidovudine or stavudine group, but the mean rate of lumbar spine BMD gain was similar between groups. At 48 weeks, all participants were offered TDF, and for the participants who were treated with the drug for 96 weeks, total body BMD z score declined by -0.338 and lumbar spine BMD z score declined by -0.012.5

Not all studies of TDF in children have identified a decline in BMD.15,16 No effect of TDF on BMD was found in a study in pediatric patients on stable therapy with undetectable viral load who were switched from stavudine and PI-containing regimens to TDF/lamivudine/efavirenz.16 All patients in this study remained clinically stable and virologically suppressed after switching to the new regimen.17

**Monitoring Potential Bone Toxicity**

The Panel does not recommend routine DXA monitoring for children or adolescents treated with TDF. Given the potential for BMD loss in children treated with TDF, some experts obtain a DXA before initiation of TDF therapy and approximately 6 months after starting TDF, especially in pre-pubertal patients and those early in puberty (i.e., Tanner Stages 1 and 2). If DXA results are abnormal consider referral to a subspecialist. Despite the ease of use of a once-daily drug and the efficacy of TDF, the potential for BMD loss during the important period of rapid bone accrual in early adolescence is concerning and favors judicious use of TDF in this age group.

**Renal**

New onset or worsening of renal impairment has been reported in adults and children receiving TDF and may be more common in those with higher tenofovir trough plasma concentrations.18 The main target of TDF nephrotoxicity is the renal proximal tubule,19 and case reports highlight the infrequent but most severe manifestations of renal Fanconi syndrome, with hypophosphatemia-associated myalgias, hypocalcemia, bone pain and fractures, reduced creatinine clearance (CrCl), and diabetes insipidus,20,21 possibly from genetic polymorphisms related to renal tubular clearance of TDF.22 Irreversible renal failure is quite rare but has been reported.23

Renal toxicity leading to discontinuation of TDF was reported in 3.7% (6 of 159) of HIV-1-infected children treated with TDF in the United Kingdom and Ireland,6 but subclinical renal tubular damage is more frequent, and increased urinary beta-2 microglobulin was identified in 27% (12 of 44) of children treated with TDF compared with 4% (2 of 48) of children not treated with TDF.24 An observational cohort study of 2,102 children with HIV in the United States suggested a twofold increased risk of renal disease (increased creatinine or proteinuria) in children treated with TDF-containing cART compared to those treated with cART not containing TDF.25 Prospectively evaluated renal function reported for 40 pediatric patients on TDF-containing cART from 5 Spanish hospitals showed that 18 patients had CrCl declines after at least 6 months of therapy; 28 patients had decreases in tubular reabsorption of phosphate worsening with longer time on TDF; and 33 patients had proteinuria, including 10 patients with proteinuria in the nephrotic range.26 TDF-associated proteinuria or chronic kidney disease is more common with longer duration of treatment.27

Of 89 participants aged 2 to 12 years who received TDF in Gilead study 352 (median drug exposure 104 weeks), four were discontinued from the study for renal tubular dysfunction, three of whom had hypophosphatemia and decrease in total body or spine BMD z score.5

**Monitoring Potential Renal Toxicity**

Because of the potential for TDF to decrease creatinine clearance and to cause renal tubular dysfunction, measurement of serum creatinine and urine dipstick for protein and glucose prior to drug initiation is recommended. In asymptomatic individuals, the optimal frequency for routine monitoring of creatinine and renal tubular function (urine protein and glucose) is unclear. Many panel members monitor creatinine with other blood tests every 3 to 4 months, and urinalysis every 6 to 12 months. Serum phosphate should be measured if clinically indicated; renal phosphate loss can occur in the presence of normal creatinine and the absence of proteinuria. Because nephrotoxicity increases with the duration of TDF treatment, monitoring should be continued during therapy with the drug.

## Zidovudine (ZDV, AZT, Retrovir)

**Formulations**
- **Capsules:** 100 mg
- **Tablets:** 300 mg
- **Syrup:** 10 mg/mL

**Concentrate for Injection or Intravenous (IV) Infusion:** 10 mg/mL

**Generic Formulations:** Zidovudine capsules, tablets, syrup, and injection are approved by the Food and Drug Administration for manufacture and distribution in the United States.

### Fixed-Dose Combination Tablets:

- **With lamivudine:**
  - 300 mg zidovudine plus 150 mg lamivudine (Combivir, generic—scored)

- **With lamivudine plus abacavir:**
  - 300 mg zidovudine plus 150 mg lamivudine plus 300 mg abacavir (Trizivir, generic)

## Dosing Recommendations

### Zidovudine: Neonates

<sup>a</sup> See **Perinatal Guidelines** for ZDV dosing for prevention of perinatal transmission.

<sup>b</sup> For infants unable to tolerate oral agents, the IV dose is reduced by 25% of the oral dose while maintaining the same dosing interval.

<sup>c</sup> See **Special Issues in Neonates**.

## Selected Adverse Events

- Bone marrow suppression: macrocytosis with or without anemia, neutropenia
- Nausea, vomiting, headache, insomnia, asthenia
- Lactic acidosis/severe hepatomegaly with hepatic steatosis
- Nail pigmentation
- Hyperlipidemia
- Insulin resistance/diabetes mellitus
- Lipoatrophy
- Myopathy

## Special Instructions

- Give zidovudine without regard to food.
- If substantial granulocytopenia or anemia develops in patients receiving zidovudine, it may be necessary to discontinue therapy until bone marrow recovery is observed. In this setting, some patients may require erythropoietin or filgrastim injections or transfusions of red blood cells.

- For infants unable to tolerate oral agents, the IV dose for newborns should be reduced by...
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Other nucleoside reverse transcriptase inhibitors (NRTIs):** Zidovudine should not be administered in combination with stavudine because of in vitro virologic antagonism.

- **Bone marrow suppressive/cytotoxic agents including ganciclovir, valganciclovir, interferon alfa, and ribavirin:** These agents may increase the hematologic toxicity of zidovudine.

- **Nucleoside analogues affecting DNA replication:** Nucleoside analogues such as ribavirin antagonize in vitro antiviral activity of zidovudine.

- **Doxorubicin:** Simultaneous use of doxorubicin and zidovudine should be avoided. Doxorubicin may inhibit the phosphorylation of zidovudine to its active form.

**Major Toxicities**

- **More common:** Hematologic toxicity, including granulocytopenia and anemia, particularly in patients with advanced HIV-1 disease. Headache, malaise, nausea, vomiting, and anorexia. Incidence of neutropenia may be increased in infants receiving lamivudine.\(^1\)

- **Less common (more severe):** Myopathy (associated with prolonged use), myositis, and liver toxicity. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported. Fat maldistribution. **Possible increased risk of cardiomyopathy.**\(^2\)

- **Rare:** Increased risk of hypospadias after first-trimester exposure to zidovudine observed in one cohort study.\(^3\) Possible association between first-trimester exposure to zidovudine and congenital heart defects.\(^4,5\)
**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

Resistance mutations were shown to be present in 29% (5 of 17) of infants born to mothers who received zidovudine during pregnancy.6

**Pediatric Use**

**Approval**

Zidovudine is frequently included as a component of the NRTI backbone for combination antiretroviral therapy (cART).7-23 Pediatric experience with zidovudine both for treatment of HIV and for prevention of perinatal transmission is extensive.

**Special Issues in Neonates**

Perinatal trial Pediatric AIDS Clinical Trial Group (PACTG) 076 established that zidovudine prophylaxis given during pregnancy, labor, and delivery, and to the newborn reduced risk of perinatal transmission of HIV by nearly 70%24 (see the Perinatal Guidelines for further discussion on the use of zidovudine for the prevention of perinatal transmission of HIV). Although the PACTG 076 study used a zidovudine regimen of 2 mg/kg every 6 hours, data from many international studies support twice daily oral infant dosing for prophylaxis. Zidovudine 4 mg/kg body weight every 12 hours is now recommended for neonates/infants ≥35 weeks of gestation for prevention of transmission or treatment (see the Perinatal Guidelines).

For full-term neonates who are diagnosed with HIV infection before age 4 weeks, the zidovudine dose should be increased at age 4 weeks to the continuation dose (see table above). HIV-exposed but uninfected infants should be continued on the initial prophylactic dose until age 6 weeks (see the Perinatal Guidelines). The activity of the enzymes responsible for glucuronidation is low at birth and increases dramatically over the first 4 to 6 weeks of life in full-term neonates.

For premature infants who are diagnosed with HIV infection, the time to change the dose to continuation dose varies with post-gestational age and clinical status of the neonate. Based on modeling and pharmacokinetics (PK) of zidovudine in premature infants, for infants born at ≥30 to <35 weeks change to 12 mg/kg/dose at post-gestational age 6 to 8 weeks and for infants <30 weeks, change to 12 mg/kg/dose at post-gestational age 8 to 10 weeks.25 Careful clinical assessment of the infant, evaluation of hepatic and renal function, and review of concomitant medications should be performed prior to increasing zidovudine dose to that recommended for full-term infants.

**Pharmacokinetics**

Overall, zidovudine PK in pediatric patients aged >3 months are similar to those in adults. Zidovudine undergoes intracellular metabolism to its active form, zidovudine triphosphate. Although the mean half-life of intracellular zidovudine triphosphate (9.1 hours) is considerably longer than that of un-metabolized zidovudine in plasma (1.5 hours), once-daily zidovudine dosing is not recommended because of low intracellular zidovudine triphosphate concentrations seen with 600-mg, once-daily dosing in adolescents.26 PK studies, such as PACTG 331, demonstrate that dose adjustments are necessary for premature infants because they have reduced clearance of zidovudine compared with term newborns of similar postnatal age.8 Zidovudine has good central nervous system (CNS) penetration (cerebrospinal fluid-to-plasma concentration ratio = 0.68) and has been used in children with HIV-related CNS disease.19

**Toxicity**

Several studies suggest that the adverse hematologic effects of zidovudine may be concentration-dependent, with a higher risk of anemia and neutropenia in patients with higher mean area under the curve.7,8
While the incidence of cardiomyopathy associated with perinatal HIV infection has decreased dramatically since the use of cART became routine, a regimen containing zidovudine may increase the risk. Recent analysis of data from a U.S.-based, multicenter prospective cohort study (PACTG 219/219C) found that ongoing zidovudine exposure was independently associated with a higher rate of cardiomyopathy.

Formulations
Capsules: 50 mg, 200 mg
Tablets: 600 mg

Fixed-Dose Combination Tablets:
With Emtricitabine and Tenofovir Disoproxil Fumarate (Tenofovir):
• Emtricitabine 200 mg + tenofovir 300 mg + efavirenz 600 mg (Atripla)

Dosing Recommendations

Neonatal Dose:
• Efavirenz is not approved for use in neonates.

Pediatric Dose:
Infants and Children Aged 3 Months to <3 Years and Weight ≥3 kg:
• The Panel recommends that efavirenz generally not be used in children aged 3 months to <3 years. If use of efavirenz is unavoidable due to the clinical situation, the Panel suggests the use of investigational doses of efavirenz in this age group. See text for investigational dosing tables; evaluation of CYP 2B6 genotype is required prior to use. Therapeutic drug monitoring is recommended with an efavirenz concentration measured 2 weeks after initiation; some experts would also measure at age 3 years when making the dose adjustment. For dose adjustment based on efavirenz concentrations, consultation with an expert is recommended.

Children Aged ≥3 Years and Weight ≥10 kg:
Administer Efavirenz Once Daily

\(^a\) The dose in mg can be dispensed in any combination of capsule strengths.

Selected Adverse Events

• Rash
• Central nervous system (CNS) symptoms such as dizziness, somnolence, insomnia, abnormal dreams, impaired concentration, psychosis, seizures, suicidality
• Increased transaminases
• False-positive with some cannabinoid and benzodiazepine tests
• Potentially teratogenic
• Lipohypertrophy, although a causal relationship has not been established and this adverse event may be less likely than with the boosted protease inhibitors

Special Instructions

• Efavirenz can be swallowed as a whole capsule or tablet or administered by sprinkling the contents of an opened capsule on food as described below.

• Administer whole capsule or tablet of Atripla on an empty stomach. Avoid administration with a high-fat meal because of potential for increased absorption.

• Bedtime dosing is recommended, particularly during the first 2 to 4 weeks of therapy, to improve tolerability of CNS side effects.

• Efavirenz should be used with caution in female adolescents and adults with reproductive potential because of the potential risk of teratogenicity.

Instructions for Use of Capsule as a Sprinkle Preparation with Food or Formula:
• Hold capsule horizontally over a small container and carefully twist to open to avoid spillage.
**Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection**

*Adolescent (Body Weight ≥40 kg)/Adult Dose:*
- 600 mg once daily

**Atripla**
- Atripla should not be used in pediatric patients <40 kg where the efavirenz dose would be excessive.

**Adult Dose:**
- One tablet once daily

- Gently mix capsule contents with 1–2 teaspoons of an age-appropriate soft food (e.g., applesauce, grape jelly, yogurt), or reconstituted infant formula at room temperature.
- Administer infant formula mixture using a 10-mL syringe.
- After administration, an additional 2 teaspoons of food or infant formula must be added to the container, stirred, and dispensed to the patient.
- Administer within 30 minutes of mixing and do not consume additional food or formula for 2 hours after administration

**Metabolism**
- Cytochrome P450 3A4 (CYP3A4) inducer/inhibitor (more inducer than inhibitor)
- CYP2B6, CYP3A4, and CYP2A6 substrate
- *Dosing of efavirenz in patients with hepatic impairment:* No recommendation is currently available; use with caution in patients with hepatic impairment.
- *Adult dose of Atripla in patients with renal impairment:* Because Atripla is a fixed-dose combination product and tenofovir and emtricitabine require dose adjustment based on renal function, Atripla should not be used in patients with creatinine clearance <50 mL/minute or in patients on dialysis.
- Interpatient variability in efavirenz exposure can be explained in part by polymorphisms in CYP450 with slower metabolizers at higher risk of toxicity (see text for information about therapeutic drug monitoring for management of mild or moderate toxicity).

**Drug Interactions** (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- *Metabolism:* Mixed inducer/inhibitor of CYP3A4 enzymes; concentrations of concomitant drugs can be increased or decreased depending on the specific enzyme pathway involved. There are multiple drug interactions. Importantly, dosage adjustment or the addition of ritonavir may be necessary when efavirenz is used in combination with atazanavir, fosamprenavir, indinavir, ritonavir-boosted lopinavir, or maraviroc.
- Before efavirenz is administered, a patient’s medication profile should be carefully reviewed for potential drug interactions with efavirenz.

**Major Toxicities**
- *More common:* Skin rash, increased transaminase levels. Central nervous system (CNS) abnormalities, such as dizziness, somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired
concentration, amnesia, agitation, depersonalization, hallucinations, euphoria, seizures, primarily reported in adults.

• **Rare:** An association between efavirenz and suicidal ideation, suicide, and attempted suicide (especially among those with a history of mental illness or substance abuse) was found in one retrospective analysis of four comparative trials in adults.

• **Potential risk of teratogenicity:** Classified as Food and Drug Administration (FDA) Pregnancy Class D, which means that there is positive evidence of human fetal risk based on studies in humans (see Pediatric Use section below; see also the Perinatal Guidelines).¹

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

**Pediatric Use**

**Approval**

Efavirenz is FDA-approved for use as part of combination antiretroviral therapy in children aged ≥3 months who weigh at least 3.5 kg.

**Pharmacokinetics: Pharmacogenomics**

Efavirenz metabolism is controlled by enzymes that are polymorphically expressed and result in large interpatient variability in drug exposure. CYP2B6 is the primary enzyme for efavirenz metabolism, and pediatric patients with the CYP 2B6 516 T/T genotype (which has an allele frequency of 20% in African Americans) have reduced metabolism resulting in higher efavirenz levels compared with those with the G/G or G/T genotype.²⁴ IMPAACT P1070 has shown that aggressive dosing with approximately 40 mg/kg using opened capsules resulted in therapeutic efavirenz concentrations in 68% of children aged <3 years with G/G or G/T genotype but excessive exposure in those with T/T genotype.⁴ Optimal dosing may require pretreatment CYP2B6 genotyping in children aged <3 years.⁴ Additional variant CYP2B6 alleles and variant CYP2A6 alleles have been found to influence efavirenz concentrations in adults and children.⁷⁻¹¹

**Pharmacokinetics and Dosing: Infants and Children Aged <3 Years**

Limited pharmacokinetic (PK) data in children aged <3 years or who weigh <13 kg have shown that it is difficult to achieve target trough concentrations in this age group.⁴¹² Hepatic enzyme activity is known to change with age. Using a pharmacometric model, the increase in oral clearance of efavirenz as a function of age is predicted to reach 90% of mature value by the age of 9 months.⁵ This maturation of oral clearance is postulated to result from an increase in the expression of CYP 2B6 with age.⁵ CYP 2B6-516-G/G genotype is associated with the greatest expression of hepatic CYP 2B6 when compared with the CYP 2B6-516-G/T or -T/T genotype.² In children with CYP 2B6-516-G/G genotype, oral clearance rate has been shown to be higher in children aged <5 years than in older children.² Efficacy data for opened capsules with contents used as sprinkles suggest acceptable palatability and bioavailability for infants and children aged <3 years. IMPAACT study P1070, an ongoing study of HIV-infected and HIV/tuberculosis-coinfected children aged <3 years, using efavirenz dosed by weight band based on CYP2B6 GG/GT versus TT genotype (see Tables 1a and 1b below), showed HIV RNA <400 copies/mL in 61% by intent to treat analysis at 24 weeks.⁴ When used without regard to genotype, doses higher than the FDA-recommended doses resulted in therapeutic efavirenz concentrations in an increased proportion of study participants with GG/GT genotypes but excessive exposure in a high proportion of those with TT genotypes.⁴ Therefore, dosing tables have been modified so that infants and young children with TT genotype will receive a reduced dose. Additional subjects will be studied to confirm that this dose is appropriate for this subset of patients. The modified doses listed in Tables 1a and 1b are under investigation.

Investigational doses are based on IMPAACT study P1070. Evaluation of CYP 2B6 genotype is required. Therapeutic drug level monitoring is recommended with a trough measured 2 weeks after initiation and at age 3 years for possible dose adjustment.

The FDA has approved efavirenz for use in infants and children aged 3 months to <3 years at doses derived from a population PK model based on data from adult subjects in PACTG 1021 and PACTG 382, and AI266-922, which is an ongoing study assessing the PK, safety, and efficacy of capsule sprinkles in children aged 3 months to 6 years (see Table 2).

The FDA-approved doses are lower than the CYP 2B6 extensive metabolizer doses and higher than the CYP 2B6 slow metabolizer doses currently under study in P1070. Further studies are needed to determine if the FDA dosing can achieve therapeutic levels for the group aged 3 months to 3 years. There is concern that FDA-approved doses may result in frequent under-dosing in CYP 2B6 extensive metabolizers. Estimates of efavirenz area under the curve (AUC) for FDA dosing using P1070 data are given in Table 3. Estimates were calculated as follows: P1070 observed AUC X (FDA dose/P1070 CYP 2B6 genotype-directed study dose). A high initial dose of efavirenz in the first version of the P1070 protocol was used to produce a target AUC of 35 to 180 mcg*h/mL, a systemic exposure similar to that shown to be safe and effective in older
children and adults. Estimates indicate that FDA-recommended doses of efavirenz will produce excessive efavirenz AUCs in 67% of slow metabolizer (SM) and sub-therapeutic AUCs in 38% of extensive metabolizer (EM) children aged <3 years, whereas CYP 2B6 genotype-directed dosing resulted in achievement of target AUCs in 83% of EM children and 89% of SM children.

The Panel recommends that efavirenz generally not be used in children aged 3 months to <3 years. If the clinical situation demands use of efavirenz, Panel members recommend determining CYP2B6 genotype (search for laboratory performing this testing at http://www.ncbi.nlm.nih.gov/gtr/labs). Patients should be classified as extensive CYP 2B6 516 GG and GT genotypes versus slow CYP 2B6 516 TT genotype metabolizers to guide dosing as indicated by the investigational doses from IMPAACT study P1070 (see Tables 1a and 1b). Whether the doses used are investigational or FDA-approved, efavirenz plasma concentrations should be measured 2 weeks post-initiation (see Role of Therapeutic Drug Monitoring). For dose adjustment, consultation with an expert is recommended. In addition, when dosing following the P1070 investigational dose recommendations, some experts would measure efavirenz concentrations at age 3 years to guide dose adjustment.

Pharmacokinetics: Children Aged ≥3 Years and Adolescents

Long-term HIV RNA suppression has been associated with maintenance of trough efavirenz concentrations >1 mcg/mL in adults. Early HIV RNA suppression in children has also been seen with higher drug concentrations. Higher efavirenz troughs of 1.9 mcg/mL were seen in subjects with HIV RNA levels ≤400 copies/mL versus efavirenz troughs of 1.3 mcg/mL in subjects with detectible virus (>400 copies/mL). In a West African pediatric study, ANRS 12103, early reduction in viral load (by 12 weeks) was greater in children with efavirenz minimum plasma concentration (Cmin) levels >1.1 mcg/mL or area under the curve (AUC) >51 mcg h/mL.

Even with the use of FDA-approved pediatric dosing in children aged ≥3 years, efavirenz concentrations can be suboptimal. Therefore, some experts recommend therapeutic drug monitoring (TDM) with efavirenz and possibly use of higher doses in young children, especially in select clinical situations such as virologic rebound or lack of response in an adherent patient. In one study in which the efavirenz dose was adjusted in response to measurement of the AUC, the median administered efavirenz dose was 13 mg/kg (367 mg/m²) and the range was from 3 to 23 mg/kg (69–559 mg/m²). A PK study in 20 children aged 10 to 16 years treated with lopinavir/ritonavir 300 mg/m² twice daily plus efavirenz 350 mg/m² once daily showed adequacy of the lopinavir trough values but suggested that the efavirenz trough was lower than PK targets. The authors therefore recommended that higher doses of efavirenz might be needed when these drugs are used together. TDM can be considered when using efavirenz in combinations with potentially complex drug interactions.
**Toxicity: Children versus Adults**

The toxicity profile for efavirenz differs for adults and children. A side effect commonly seen in children is rash, which was reported in up to 40% of children compared with 27% of adults. The rash is usually maculopapular, pruritic, and mild to moderate in severity and rarely requires drug discontinuation. Onset is typically during the first 2 weeks of treatment. Although severe rash and Stevens-Johnson syndrome have been reported, they are rare. In adults, CNS symptoms have been reported in more than 50% of patients. These symptoms usually occur early in treatment and rarely require drug discontinuation, but they can sometimes occur or persist for months. Bedtime efavirenz dosing appears to decrease the occurrence and severity of these neuropsychiatric side effects. For patients who can swallow capsules or tablets, ensuring that efavirenz is taken on an empty stomach also reduces the occurrence of neuropsychiatric adverse effects.

An association between efavirenz and suicidal ideation, suicide, and attempted suicide (especially among those with a history of mental illness or substance abuse) was found in one retrospective analysis of four comparative trials in adults. In several studies, the incidence of neuropsychiatric adverse effects was correlated with efavirenz plasma concentrations and the symptoms occurred more frequently in patients receiving higher concentrations. In patients with pre-existing psychiatric conditions, efavirenz should be used cautiously for initial therapy. Adverse CNS effects occurred in 14% of children receiving efavirenz in clinical studies and in 30% of children with efavirenz concentrations greater than 4 mcg/mL. CNS adverse effects may be harder to detect in children because of the difficulty in assessing neurologic symptoms such as impaired concentration, sleep disturbances, or behavior disorders in these patients.

**Toxicity: Potential Risk of Teratogenicity**

Prenatal efavirenz exposure has been associated with CNS congenital abnormalities in the offspring of cynomolgus monkeys. As of July 2010, the Antiretroviral Pregnancy Registry has received prospective reports of 792 pregnancies exposed to efavirenz-containing regimens, nearly all of which were first-trimester exposures (718 pregnancies). Birth defects occurred in 17 of 604 live births (first-trimester exposure) and 2 of 69 live births (second/third-trimester exposure). One of these prospectively reported defects with first-trimester exposure was a neural tube defect. A single case of anophthalmia with first trimester exposure to efavirenz has also been prospectively reported; however, this case included severe oblique facial clefts and amniotic banding, a known associate with anophthalmia. There have been six retrospective reports of findings consistent with neural tube defects, including meningomyelocele. All mothers were exposed to efavirenz-containing regimens in the first trimester. Although a causal relationship has not been established between these events and use of efavirenz, similar defects have been observed in preclinical studies of efavirenz. Based on these types of reports, efavirenz has been classified as FDA Pregnancy Class D, which means that there is positive evidence of human fetal risk based on studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

A recent updated meta-analysis found no association with the potential for teratogenicity following first-trimester efavirenz exposure. However, because of the low incidence of CNS anomalies in the overall population and relatively small number of exposures in the current literature, continued birth outcomes prospective surveillance is warranted. Although the data on the use of efavirenz in pregnancy are reassuring, many experts remain reluctant to consider use of efavirenz in adolescents who are trying to conceive or who are not using effective birth control, so as to avoid the use of efavirenz during the first trimester of pregnancy (the primary period of fetal organogenesis). Women of childbearing potential should undergo pregnancy testing before initiation of efavirenz and should be counseled about the potential risk to the fetus and desirability of avoiding pregnancy. Alternate antiretroviral regimens that do not include efavirenz should be strongly considered in women who are planning to become pregnant or who are sexually active and not using effective contraception (if such alternative regimens are acceptable to provider and patient and will not compromise a woman’s health). See Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States.
Therapeutic Drug Monitoring

Note: See Role of Therapeutic Drug Monitoring.

In the setting of potential toxicity, it is reasonable for a clinician to use TDM to determine whether the toxicity is due to an efavirenz concentration in excess of the normal therapeutic range. This is the only setting in which dose reduction would be considered appropriate management of drug toxicity, and even then, it should be used with caution. Also, the Panel recommends TDM when dosing efavirenz in children aged 3 months to <3 years due to variable PK properties in this young age group. An efavirenz concentration, preferably a trough, measured 2 weeks after initiation, and consultation with an expert, is recommended for dose adjustment. Long-term HIV RNA suppression has been associated with maintenance of trough efavirenz concentrations greater than 1000 ng/mL in adults. In addition, some experts would measure efavirenz concentrations at age 3 years for potential dose adjustment if dosing was initiated at age <3 years using investigational dose recommendations.

**Adult Dose (Antiretroviral-Experienced Patients):**
- 200 mg twice daily following a meal

**Selected Adverse Events**

- Nausea
- Rash, including Stevens-Johnson syndrome
- Hypersensitivity reactions have been reported, characterized by rash, constitutional findings, and sometimes organ dysfunction, including hepatic failure.
- Diarrhea

**Special Instructions**

- Always administer etravirine following a meal. Area under the curve of etravirine is decreased by about 50% when the drug is taken on an empty stomach. The type of food does not affect the exposure to etravirine.
- Etravirine tablets are sensitive to moisture; store at room temperature in original container with desiccant.
- Patients unable to swallow etravirine tablets may disperse the tablets in liquid, as follows: Place the tablet(s) in 5 mL (1 teaspoon) of water, or at least enough liquid to cover the medication and stir well until the water looks milky. If desired, add more water or alternatively orange juice or milk. **Note:** Patients should not place the tablets in orange juice or milk without first adding water. The use of grapefruit juice, warm (>40°C) drinks, or carbonated beverages should be avoided. Drink immediately, then rinse the glass several times with water, orange juice, or milk and completely swallow the rinse each time to make sure the entire dose is consumed.
- Dosing of etravirine in patients with hepatic impairment: No dosage adjustment is necessary for patients with mild-to-moderate hepatic insufficiency. No dosing information is available for patients with severe hepatic impairment.
Drug Interactions

(see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- Etravirine is associated with multiple drug interactions. Before administration, the patient’s medication profile should be carefully reviewed for potential drug interactions with etravirine.
- Etravirine should not be co-administered with the following antiretroviral (ARV) drugs: tipranavir/ritonavir, fosamprenavir/ritonavir, and unboosted protease inhibitors (PIs). It should not be administered with other non-nucleoside reverse transcriptase inhibitors (NNRTIs) (i.e., nevirapine, efavirenz, or rilpivirine). Limited data in adults suggest that etravirine may reduce the trough concentration of raltegravir, but no dose adjustment is currently recommended when etravirine and raltegravir are used together. Etravirine significantly reduces plasma concentrations of dolutegravir; dolutegravir should only be used with etravirine when co-administered with atazanavir/ritonavir, darunavir/ritonavir, or lopinavir/ritonavir.

Major Toxicities

- More common: Nausea, diarrhea, and mild rash. Rash occurs most commonly in the first 6 weeks of therapy. Rash generally resolves after 1 to 2 weeks on continued therapy. A history of NNRTI-related rash does not appear to increase the risk of developing rash with etravirine. However, patients who have a history of severe rash with prior NNRTI use should not receive etravirine.
- Less common (more severe): Peripheral neuropathy, severe rash including Stevens-Johnson syndrome, hypersensitivity reactions (HSRs) (including constitutional findings and sometimes organ dysfunction including hepatic failure), and erythema multiforme have been reported. Discontinue etravirine immediately if signs or symptoms of severe skin reactions or HSRs develop (including severe rash or rash accompanied by fever, general malaise, fatigue, muscle or joint aches, blisters, oral lesions, conjunctivitis, facial edema, hepatitis, eosinophilia). Clinical status including liver transaminases should be monitored and appropriate therapy initiated. Delay in stopping etravirine treatment after the onset of severe rash may result in a life-threatening reaction. It is recommended that patients who have a prior history of severe rash with nevirapine or efavirenz not receive etravirine.

Resistance

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).
Pediatric Use

Approval

Etravirine is Food and Drug Administration-approved for use in ARV-experienced children and adolescents aged 6 to 18 years.

Efficacy in Clinical Trials

The PIANO study (TMC125-C213) was a single-arm, Phase II trial involving 101 ARV treatment-experienced, HIV-1 infected pediatric participants aged 6 to <18 years and weighing ≥16 kg. Participants eligible for this trial were on an ARV regimen with confirmed plasma HIV-1 RNA of at least 500 copies/mL and viral susceptibility to etravirine at screening. All patients received etravirine with an investigator-selected, optimized background regimen of a ritonavir-boosted PI plus nucleoside/nucleotide analogue reverse transcriptase inhibitors and optional enfuvirtide and/or raltegravir. At Week 24, 67% of these pediatric participants had plasma HIV-1 RNA concentrations <400 copies/mL and 52% had <50 copies/mL. At week 48, 56% of the participants had <50 copies/mL, with a mean CD4 T lymphocyte cell increase of 156 x10⁶/mm³.² A greater fraction of children aged 6 to <12 years had plasma HIV-1 RNA <50 copies/mL than adolescents aged 12 to <18 years (68% versus 48%), which the investigators attributed to less advanced disease, less prior NNRTI experience at baseline, and better adherence among the children. However, the population pharmacokinetic (PK) data from this Phase II trial (101 treatment-experienced children aged 6–17 years) revealed slightly lower etravirine exposures in adolescents (aged 12–17 years) compared with children aged 6 to 11 years and with adults (see below).

The safety, efficacy, and tolerability of etravirine in treatment-experienced patients was also evaluated in a multicenter retrospective study of 23 multidrug-resistant pediatric patients with a median age of 14.2 years (interquartile range 12.5 to 15.8 years).³ The backbone regimen included at least 2 fully active drugs in 91% of patients. During a median of 48.4 weeks of follow-up, 20 patients (87%) achieved HIV-1 RNA <400 copies/mL and 18 of 23 (78%) achieved HIV-1 RNA <50 copies/mL. No patients showed complete resistance to etravirine after follow up but 3 of the 21 patients who interrupted etravirine treatment because of virological or immunological failure had single resistance mutations at baseline.

The efficacy of etravirine-containing regimens in children who have previously been treated with an NNRTI is unclear. However, in a multicenter retrospective study involving genotypic resistance data from 120 children at eight pediatric centers in Thailand, Puthanakit, et al.⁴ found that 98% of the children had at least one NNRTI resistance mutation, and 48% had etravirine mutation-weighted scores ≥4, which would be predicted to compromise its effectiveness.

Pharmacokinetics

In a Phase I dose-finding study involving children aged 6 to 17 years, 17 children were given 4 mg/kg twice daily. The PK parameters AUC₁₂h and Cₘᵢₙ were below preset statistical targets based on prior studies involving adults.⁵ Based on acceptable PK parameters, the higher dose (5.2 mg/kg twice daily; maximum 200 mg per dose) was chosen for evaluation in the Phase II PIANO study. Exposures remained lower in older adolescents than in adults and younger children, and Asians compared to either white or black participants.⁶

Key to Acronyms: AUC₀-₁₂h = Area under the curve for 12 hours post-dose; C₀ₜₜ = pre-dose concentration during chronic administration
Etravirine is often combined with ritonavir-boosted darunavir for treatment of HIV-infected adults with prior virologic failure. King et al. examined PK data from 37 pediatric patients receiving this combination, all receiving the maximum 200-mg etravirine dose. For both drugs, the estimated 90% confidence intervals for AUC and $C_{\text{min}}$ fell below targeted lower limits defined using data from studies in adults. While this combination has been effective in a small cohort of HIV-infected adolescents, and in 51% of participants in the PIANO study, these data suggest a need for additional study of PK interactions involving etravirine and other ARV agents in pediatric patients, including regimens that do not include ritonavir-boosted PIs.

**Toxicity**

In the PIANO study, rash and diarrhea were the most common adverse drug reactions. Rash ($\geq$ Grade 2) occurred in 13% of pediatric subjects and emerged at a median of 10 days, lasting a median of 7 days. Rash was observed more frequently in female subjects (17 of 64; 26.6%) than in male subjects (6 of 37; 16.2%). Etravirine was discontinued due to rash in 4 (4%) individuals, all of whom were female. Diarrhea occurred in 3 (3%) and was only reported in adolescents.

Formulations

Tablets: immediate-release 200 mg, extended-release (XR) 100 mg, and 400 mg
Suspension: 10 mg/mL

Generic Formulations:

Tablets: immediate-release 200 mg, extended-release (ER) 400 mg only
Suspension: 10 mg/mL

Dosing Recommendations

Neonate/Infant Dose (≤14 Days):
When used for prevention of perinatal transmission of HIV (see Perinatal Guidelines).

Treatment of HIV Infection:
Pediatric Dose: Immediate Release and Suspension Formulations

≤8 Years:

- INVESTIGATIONAL DOSE age <1 month: 6 mg/kg/dose twice daily (no lead-in). (See Dosing: Special Considerations: Neonates ≤14 Days and Premature Infants.)
- ≤1 month to <8 years: 200 mg/m² of BSA/dose (maximum dose of immediate release tablets is 200 mg twice daily).

≥8 Years:

- 120–150 mg/m² BSA/dose (maximum dose of immediate release tablets is 200 mg twice daily or extended release tablets 400 mg once daily).
- When adjusting the dose for a growing child, the mg dose need not be decreased as the child reaches age 8 years; rather, the mg dose is left static to achieve the appropriate mg-per- m² dosage as the child grows, as long as there are no untoward effects.

Note: Please see note at bottom of table.

Pediatric Dose Extended-Release Formulation (>6 Years)

- Patients ≥6 years who are already taking immediate-release nevirapine twice daily can be switched to nevirapine extended release without lead-in dosing.

Note: Please see note at bottom of table.

Selected Adverse Events

- Rash, including Stevens-Johnson syndrome
- Symptomatic hepatitis, including fatal hepatic necrosis
- Severe systemic hypersensitivity syndrome with potential for multisystem organ involvement and shock

Special Instructions

- Shake suspension well before administering and store at room temperature.
- Can be given without regard to food.
- Nevirapine-associated skin rash usually occurs within the first 6 weeks of therapy. If rash occurs during the initial 14 day lead-in period, do not increase dose until rash resolves (see Major Toxicities section).
- Nevirapine extended-release tablets must be swallowed whole. They cannot be crushed, chewed, or divided.
- If nevirapine dosing is interrupted for >14 days, nevirapine dosing should be restarted with once-daily dosing for 14 days, followed by escalation to the full, twice-daily regimen (see Dosing Considerations: Lead-In Requirement).
- Most cases of nevirapine-associated hepatic toxicity occur during the first 12 weeks of therapy; frequent clinical and laboratory monitoring, including liver function tests (LFTs), is important during this period (see Major Toxicities).

Metabolism

- Metabolized by cytochrome P450 (3A inducer); 80% excreted in urine

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection  P-54
Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

Adolescent/Adult Dose:
- 200 mg twice daily or 400 mg extended release once daily.

Note: Nevirapine is initiated at a lower dose and increased in a stepwise fashion to allow induction of cytochrome P450 metabolizing enzymes, which results in increased drug clearance. The occurrence of rash is diminished by this stepwise increase in dose. Initiate therapy with the age-appropriate dose of the immediate-release formulation once daily (half daily dose) for the first 14 days of therapy. If there is no rash or untoward effect, at 14 days of therapy, increase to the age-appropriate full dose, administered once daily, of the extended-release preparation. However, in children aged ≤2 years some experts initiate nevirapine without a lead-in (see Dosing Considerations: Lead-In Requirement). In patients already receiving full-dose immediate-release nevirapine, extended release tablets can be used without the 200-mg lead-in period. Patients must swallow nevirapine extended release tablets whole. They must not be chewed, crushed, or divided. Patients must never take more than one form of nevirapine at the same time. Dose should not exceed 400 mg daily.

Nevirapine In Combination with Ritonavir-Boosted Lopinavir:
- A higher dose of ritonavir-boosted lopinavir may be needed. See Ritonavir-Boosted Lopinavir section.

Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- Metabolism: Induces hepatic cytochrome P450 including 3A (CYP3A) and 2B6; auto-induction of metabolism occurs in 2 to 4 weeks, with a 1.5- to 2-fold increase in clearance. There is potential for multiple drug interactions. Mutant alleles of CYP2B6 cause increases in nevirapine serum concentration in a similar manner but to a lesser extent than efavirenz. Altered adverse effect profiles related to elevated nevirapine levels have not been documented probably because there are alternative CYP metabolic pathways for nevirapine. Please see Efavirenz section for further details.
- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions. Nevirapine should not be co-administered to patients receiving atazanavir (with or

(glucuronidated metabolites).
- Dosing of nevirapine in patients with renal failure receiving hemodialysis: An additional dose of nevirapine should be given following dialysis.
- Dosing of nevirapine in patients with hepatic impairment: Nevirapine should not be administered to patients with moderate or severe hepatic impairment.
without ritonavir). Nevirapine increases the metabolism of lopinavir and dosage adjustment is recommended (see Ritonavir-Boosted Lopinavir section).

Major Toxicities

Note: These are seen with continuous dosing regimens, not single-dose nevirapine prophylaxis.

- **More common:** Skin rash (some severe and requiring hospitalization; some life-threatening, including Stevens-Johnson syndrome and toxic epidermal necrolysis), fever, nausea, headache, and abnormal hepatic transaminases. Nevirapine should be permanently discontinued and not restarted in children or adults who develop severe rash, rash with constitutional symptoms (i.e., fever, oral lesions, conjunctivitis, or blistering), or rash with elevated hepatic transaminases. Nevirapine-associated skin rash usually occurs within the first 6 weeks of therapy. If rash occurs during the initial 14-day lead-in period, do not increase dose until rash resolves. However, the risk of developing nevirapine resistance with extended lead-in dosing is unknown and is a concern that must be weighed against a patient’s overall ability to tolerate the regimen and the current antiviral response.

- **Less common (more severe):** Severe, life-threatening, and in rare cases fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure (these are less common in children than adults). The majority of cases occurs in the first 12 weeks of therapy and may be associated with rash or other signs or symptoms of hypersensitivity reaction. Risk factors for nevirapine-related hepatic toxicity in adults include baseline elevation in serum transaminase levels, hepatitis B or hepatitis C infection, female gender, and higher CD4 T lymphocyte (CD4) cell count at time of therapy initiation (CD4 cell count >250 cells/mm³ in adult females and >400 cells/mm³ in adult males). In children, there is a 3-fold increased risk of rash and hepatotoxicity when children initiate nevirapine with a CD4 percentage >15%.² Hypersensitivity reactions have been reported, including, but not limited to, severe rash or rash accompanied by fever, blisters, oral lesions, conjunctivitis, facial edema, muscle or joint aches, general malaise, and significant hepatic abnormalities. Nevirapine should be permanently discontinued and not restarted in children or adults who develop symptomatic hepatitis, severe transaminase elevations, or hypersensitivity reactions.

Resistance

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see http://www.iasusa.org/resistance_mutations/index.html) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR).

Pediatric Use

Approval

Nevirapine is Food and Drug Administration (FDA)-approved for treatment of HIV in children from infancy (aged ≥15 days) onward and remains a mainstay of therapy especially in resource-limited settings.³⁻¹¹ The extended-release tablet formulation has been FDA-approved for use in children aged ≥6 years.

Efficacy

In infants and children previously exposed to single-dose nevirapine for prevention of perinatal transmission; nevirapine-based, combination antiretroviral therapy (cART) is less likely than ritonavir-boosted lopinavir-based cART to control virus load. In a large randomized clinical trial, P1060, 153 children (mean age 0.7 years) previously exposed to nevirapine for perinatal prophylaxis were treated with zidovudine plus lamivudine plus the randomized addition of nevirapine versus ritonavir-boosted lopinavir. At 24 weeks post-randomization, 24% of children in the zidovudine/lamivudine/nevirapine arm reached a virologic endpoint (virologic failure defined as <1 log decrease in HIV RNA in Weeks 12–24 or HIV RNA >400 copies/mL at Week 24) compared with 7% in the zidovudine/lamivudine/ritonavir-boosted lopinavir, \( P = 0.0009 \). When all primary endpoints were considered, including viral failure, death, and treatment discontinuation, the protease inhibitor arm remained superior because 40% of children in the nevirapine arm met a primary endpoint.
versus 22% for the ritonavir-boosted lopinavir arm, \( P = 0.027 \). Similar results were reported in a comparison study of nevirapine versus ritonavir-boosted lopinavir in children aged 6 to 36 months not previously exposed to nevirapine, suggesting that ritonavir-boosted lopinavir-based therapy is superior to nevirapine-based therapy for infants, regardless of past nevirapine exposure.\(^{13}\)

Extended-release nevirapine (400-mg tablets) was approved by the FDA for use in adult patients based on two trials: VERxVE and TRANxITION. VERxVE\(^{14}\) enrolled treatment-naive adults who received 200 mg of immediate-release nevirapine for 14 days before commencing daily dosing of nevirapine extended release or standard twice-daily dosing of immediate-release tablets. A backbone of tenofovir and emtricitabine was used. TRANxITION enrolled patients already receiving full-dose immediate-release nevirapine and randomized them to receive the extended-release tablets or to remain on their current nevirapine regimen. Both studies have shown equivalent efficacy, adverse effect, and CD4 profiles through 144 weeks.\(^{15-17}\) Trial 1100.1518 was an open-label, multiple-dose, non-randomized, crossover trial performed in 85 HIV-1 infected pediatric participants aged 3 years to <18 years who had received at least 18 weeks of immediate-release nevirapine and had plasma HIV-1 RNA <50 copies per mL prior to trial enrollment. Participants were stratified according to age (3 to <6 years, 6 to <12 years, and 12 to <18 years). Following a 10-day period with immediate-release nevirapine, participants were treated with nevirapine extended-release tablets once daily in combination with other antiretroviral (ARV) drugs for 10 days, after which steady-state pharmacokinetics (PK) were determined. Forty participants who completed the initial part of the study were enrolled in an optional extension phase of the trial, which evaluated the safety and antiviral activity of nevirapine extended release through a minimum of 24 weeks of treatment. Of the 40 participants who entered the treatment extension phase, 39 completed at least 24 weeks of treatment. After 24 weeks or more of treatment with nevirapine extended release, all 39 participants continued to have plasma HIV-1 RNA <50 copies per mL. This dosage form was approved for use in children aged \( \geq 6 \) years in November 2012.

**General Dosing Considerations**

Body surface area (BSA) has traditionally been used to guide nevirapine dosing in infants and young children. It is important to avoid under-dosing of nevirapine because a single point mutation (K103N) in the HIV genome may confer non-nucleoside reverse transcriptase inhibitor resistance to both nevirapine and efavirenz. Younger children (\( \leq 8 \) years of age) have higher apparent oral clearance than older children and require a higher dosage to achieve equivalent drug exposure compared with children aged \( >8 \) years.\(^{8,9}\)

Because of this, it is recommended that dosing for children younger than age 8 years be 200 mg/m\(^2\) of BSA per dose when given twice daily (immediate-release tablet maximum dose 200 mg twice daily) or 400 mg/m\(^2\) of body surface area per dose when administered once daily as the extended-release preparation (maximum dose of the extended release preparation 400 mg/dose once daily). For children aged 8 years and older, the recommended dose is 120 mg/m\(^2\) of BSA per dose (maximum dose 200 mg) administered twice daily to a maximum of 400 mg once daily when the extended-release preparation is used in children aged \( \geq 6 \) years. When adjusting the dose in a growing child, the milligram dose need not be decreased (from 200 mg/m\(^2\) to 120 mg/m\(^2\)) as the child reaches 8 years; rather, the milligram dose is left static as long as there are no untoward effects, and the dose is allowed to achieve the appropriate mg/m\(^2\) dosage as the child grows. Some practitioners dose nevirapine at 150 mg/m\(^2\) of BSA every 12 hours or 300 mg/m\(^2\) per dose once daily if using the extended-release preparation (maximum of 200 mg per dose twice daily of the immediate-release tablets or 400 mg per dose once daily of the extended release tablets) regardless of age, as recommended in the FDA-approved product label.

**Dosing Considerations: Lead-In Requirement**

One explanation for the poorer performance of nevirapine in the P1060 trial was the potential for under-dosing during the lead-in period. This potential for under-dosing with an increased risk of resistance has led to the re-evaluation of lead-in dosing in children who are naïve to nevirapine therapy. Traditional dosing of nevirapine is initiated with an age-appropriate dose once daily (200 mg/m\(^2\) in infants \( \geq 15 \) days and children \(<8 \) years using the immediate release preparations) during the first 2 weeks of treatment to allow for the
auto-induction of the liver enzymes CYP3A and CYP2B6, which are involved in nevirapine metabolism. Studies, largely in adult cohorts, previously indicated the potential for greater drug toxicity without this lead-in.18 The CHAPAS-1 Trial19 randomized 211 children to initiate cART with nevirapine without a lead-in (age-appropriate dose, twice daily, of the immediate-release preparation) or with a lead-in (age-appropriate dose, once daily, of the immediate-release preparation) for 2 weeks followed by standard twice-daily dosing of the immediate release preparation. Children were followed for a median of 92 weeks (68–116), and there was no difference in grade 3 or 4 adverse events between the two groups. The group initiating nevirapine without a lead-in had a statistically significant increase in grade 2 rash, but the majority of participants were able to continue nevirapine therapy after a brief interruption. CD4 and virologic endpoints were no different through 96 weeks. In a sub-study of this trial, the investigators evaluated nevirapine plasma concentrations 3 to 4 hours after a morning dose of nevirapine after 2 weeks of therapy. For children <2 years of age, 13% (3/23) initiating at full dose versus 32% (7/22) initiating at half dose had subtherapeutic nevirapine levels (<3 mg/L) at 2 weeks ($P = 0.16$). There were no rash events in the substudy group aged <2 years and in the parent CHAPAS study there was a strong age effect on rash occurrence (increased risk with increasing age), suggesting that a lead-in dose may not be necessary in young patients.20 Reinitiating half-dose nevirapine for another 2 weeks in those children who have interrupted therapy for 7 days or longer has been standard practice; however, given the current understanding of nevirapine resistance, the half-life of the CYP enzymes,21 and the results of CHAPAS-1, the panel recommends restarting full-dose nevirapine in children who interrupt therapy for 14 days or less.

**Dosing: Special Considerations: Neonates and Premature Infants**

For neonates and for premature infants (until 42 weeks corrected gestational age), PK data are currently inadequate to formulate an effective complete cART regimen. Although dosing is available for zidovudine and lamivudine, data are inadequate for other classes of cART. Based on PK modeling, an investigational dose of 6 mg/kg administered twice daily for nevirapine has been proposed for full-term infants diagnosed as infected in the first few days of life. Because modeling data included infants up to 1 month and target values were reached using the investigational dose, a single dosing recommendation of 6 mg/kg/BID for the first month of life was chosen by the Panel to prevent repeated dose changing requirements. Pharmacokinetics of nevirapine using the investigational dose will be evaluated as part of an IMPAACT protocol. Providers considering treatment of infants <2 weeks or premature infants should contact a pediatric HIV expert for guidance because the decision about whether to treat and what to use will involve weighing the risks and benefits of using unapproved cART dosing, and incorporating case-specific factors such as exposure to ARV prophylaxis.

**References**

Rilpivirine (RPV, Edurant, TMC 278) *(Last updated April 27, 2015; last reviewed April 27, 2015)*

For additional information see Drugs@FDA: [http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm](http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm)

**Formulations**

**Tablet:** 25 mg  
**Fixed-Dose Combination Tablet:**  
*With emtricitabine and tenofovir disoproxil fumarate (tenofovir):*  
- Rilpivirine 25 mg + emtricitabine 200 mg + tenofovir 300 mg (Complera)

### Dosing Recommendations

**Neonate/Infant Dose:**  
- Not approved for use in neonates/infants.

**Pediatric Dose:**  
- Not approved for use in children. A clinical trial in treatment-naive adolescents (aged 12–18 years) is under way using a 25-mg dose.

**Adolescent (>18 years)/Adult Dose**  
*Antiretroviral-Naive Patients with HIV RNA ≤100,000 copies/mL or Virologically-Suppressed (HIV RNA <50 copies/mL) Patients with No History of Virologic Failure or Resistance to Rilpivirine and Other ARVs and Currently on Their First or Second Regimen:*  
- 25 mg once daily

**Combination Tablet:**  
*Complera (Tenofovir with Emtricitabine plus Rilpivirine):*  
- Adult dose (aged ≥18 years): 1 tablet once daily in treatment-naive adults with baseline viral load <100,000 copies/mL or virologically suppressed adults with no history of virologic failure or resistance to rilpivirine and other ARVs and currently on their first or second regimen.

### Selected Adverse Events

- Depression, mood changes
- Insomnia
- Headache
- Rash
- Hepatotoxicity

### Special Instructions

- Patients **must be able** to take rilpivirine with a meal of at least **400 calories on a regular schedule** (a protein drink alone does not constitute a meal).
- Do not use rilpivirine with other non-nucleoside reverse transcriptase inhibitors.
- Do not use rilpivirine with proton pump inhibitors.
- Antacids should only be taken either at least 2 hours before or at least 4 hours after rilpivirine.
- Use rilpivirine with caution when co-administered with a drug with a known risk of torsades de pointes (see [https://www.crediblemeds.org/](https://www.crediblemeds.org/)).
- Do not start rilpivirine in patients with HIV RNA >100,000 copies/mL because of increased risk of virologic failure.

### Metabolism

- Cytochrome P450 (CYP) 3A substrate
- **Dosing in patients with hepatic impairment:** No dose adjustment is necessary in patients with mild or moderate hepatic impairment.
- Rilpivirine decreases tubular secretion of creatinine and slightly increases measured
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Metabolism:** Rilpivirine is a CYP 3A substrate and requires dosage adjustments when administered with CYP 3A-modulating medications.
- Before rilpivirine is administered, a patient’s medication profile should be carefully reviewed for potential drug interactions.
- Co-administration of rilpivirine with drugs that increase gastric pH may decrease plasma concentrations of rilpivirine.
- Antacids should only be taken either at least 2 hours before or at least 4 hours after rilpivirine.
- H2-receptor antagonists should only be administered at least 12 hours before or at least 4 hours after rilpivirine.
- Rifabutin and rifampin significantly reduce rilpivirine plasma concentrations; therefore, co-administration of rifabutin or rifampin with rilpivirine is contraindicated.

Major Toxicities

- **More common:** Insomnia, headache, and rash
- **Less common (more severe):** Depression or mood changes

Resistance

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

Pediatric Use

**Approval**

Rilpivirine is approved in combination with other antiretroviral (ARV) agents for treatment-naive, HIV-infected adults with viral load \( \leq 100,000 \text{ copies/mL} \). In addition, the combination tablet rilpivirine/emtricitabine/tenofovir (Complera) is approved in virologically-suppressed patients (HIV RNA <50 copies/mL) on their first or second regimen with no history of virologic failure or resistance to non-nucleoside reverse transcriptase inhibitors (NNRTIs).

**Pharmacokinetics**

The pharmacokinetics (PK), safety, and efficacy of rilpivirine in pediatric patients have not been established. An international (India, Thailand, Uganda, and South Africa) Phase II trial, Pediatric Study in Adolescents
Investigating a New NNRTI TMC278 (PAINT) is investigating a 25-mg dose of rilpivirine in combination with 2 nucleoside reverse transcriptase inhibitors in ARV-naive adolescents aged 12 to <18 years who weigh ≥32 kg and have a viral load ≤100,000 copies/mL.¹

In the dose-finding phase of the study 11 youth aged >12 to ≤15 years and 12 youth aged >15 to ≤18 years underwent intensive PK evaluations after an observed dose of rilpivirine taken with a meal. Results and adult comparison data are listed in the table below.²

*Correction provided by personal communication via email from Herta Crauwels, November 11, 2014.

**Key to Acronyms:** AUC = area under the curve; CI = confidence interval; Cmax = maximum plasma concentration; Cmin = minimum plasma concentration; PK = pharmacokinetic

In a PK study of youth aged 13 to 23 years receiving rilpivirine,³ rilpivirine exposure was slightly higher than results from PAINT in those receiving 25 mg rilpivirine without darunavir/ritonavir (AUC = 2380 ngxh/mL) and substantially higher in those receiving 25 mg rilpivirine with darunavir/ritonavir (AUC = 6740 ngxh/mL). No dose adjustments are currently recommended for adults when rilpivirine is used in combination with darunavir/ritonavir, where a similar 2- to 3-fold increase in rilpivirine exposure has been reported.⁴

**Toxicity**

In the PAINT study the observed adverse events were similar to those reported in adults. Eight adverse events were reported in 5 of 25 participants as being at least possibly related to rilpivirine (e.g., somnolence, nausea, upper abdominal pain, fever, dizziness, headache); all were grade 1 in severity.

Formulations

**Powder Packet:** 50 mg/packet

**Capsules:** 150 mg, 200 mg, and 300 mg

**Fixed-Dose Combination Tablets:**

*With cobicistat:*

- 300 mg atazanavir plus 150 mg cobicistat (Evotaz)

**Capsules and powder packets are not interchangeable.**

---

**Dosing Recommendations**

**Neonate:**
- Not approved for use in neonates and infants <3 months. Atazanavir should not be administered to neonates because of risks associated with hyperbilirubinemia (kernicterus).

**Pediatric Dose:**

*Powder Formulation:*a

- Powder formulation must be administered with ritonavir.
- Not approved for use in infants <3 months or weight <10 kg or children weighing ≥25 kg

**Infants and Children (Aged ≥3 Months; Weight >10 kg and <25 kg):**

**Atazanavir Powder**

<table>

*a* mg/kg dosing is higher for the powder packets than for the capsules. Bioavailability is higher for the capsules than for the powder when studied in adults.

*b* For a child who cannot swallow atazanavir capsules, the Panel advises increasing to an experimental dose of 300 mg atazanavir powder plus ritonavir oral solution 80 mg, both once daily with food. This dose is being studied in children who weigh 25 to <35 kg (see text).

**Selected Adverse Events**

- Indirect hyperbilirubinemia
- Prolonged electrocardiogram (ECG) PR interval, first-degree symptomatic atrioventricular (AV) block in some patients
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia
- Nephrolithiasis
- Skin rash
- Increased serum transaminases
- Hyperlipidemia (primarily with ritonavir boosting)

**Special Instructions**

- Administer atazanavir with food to enhance absorption.
- Capsules and powder packets are not interchangeable.
- Do not open capsules.
- **Powder Administration:**
  - Mix atazanavir oral powder with at least 1 tablespoon of food such as applesauce or yogurt. Oral powder mixed with a beverage (at least 30 mL of milk or water) may be used for older infants who can drink from a cup. For young infants (<6 months) who cannot eat solid food or drink from a cup, oral powder should be mixed with at least 10 mL of infant formula and given using an oral dosing syringe.
Capsule Formulation:• Not approved for use in children <6 years or <15 kg

Children (≥6 to <18 Years; Weight ≥15 kg):

Atazanavir Capsulesc

c mg/kg dosing is higher for the powder packets than for the capsules. Bioavailability is higher for the capsules than for the powder when studied in adults. While not studied in age <6 years, Panel advises that capsules can be used when transitioning from powder in children who can swallow capsules (see text).
d Either ritonavir capsules or ritonavir oral solution can be used.
e Some experts would increase atazanavir to 300 mg at ≥35 kg to avoid underdosing, especially when administered with tenofovir (see text for discussion).

For Treatment-Naive Pediatric Patients who do not Tolerate Ritonavir:

• Atazanavir powder must be administered with ritonavir.
• For capsule formulation, atazanavir/ritonavir is preferred for children and adolescents. Current Food and Drug Administration (FDA)-approved prescribing information does not recommend unboosted atazanavir in children aged <13 years. If unboosted atazanavir is used in adolescents, higher doses than those used in adults may be required to achieve target drug concentrations (see Pediatric Use).
• Only atazanavir/ritonavir should be used in combination with tenofovir disoproxil fumarate (tenofovir) because tenofovir decreases atazanavir exposure.

Adolescent (Aged ≥18 to 21 Years)/Adult Dose

Antiretroviral-Naive Patients:

• Atazanavir 300 mg plus ritonavir 100 mg once daily with food
• Atazanavir 300 mg plus cobicistat/ 150 mg, both once daily with food or as co-formulated

• Administer ritonavir immediately following powder administration.
• Administer the entire dosage of oral powder within 1 hour of preparation.

Because atazanavir can prolong the ECG PR interval, use atazanavir with caution in patients with pre-existing cardiac conduction system disease or with other drugs known to prolong the PR interval (e.g., calcium channel blockers, beta-blockers, digoxin, verapamil).

Atazanavir absorption is dependent on low gastric pH; therefore, when atazanavir is administered with medications that alter gastric pH, special dosing information is indicated (see Drug Interactions for recommendations on dosing atazanavir when the drug is co-administered with H2 receptor antagonists). When administered with buffered didanosine formulations or antacids, give atazanavir at least 2 hours before or 1 hour after antacid or didanosine administration.

The plasma concentration, and therefore therapeutic effect, of atazanavir can be expected to decrease substantially when atazanavir is co-administered with proton-pump inhibitors (PPIs). Antiretroviral therapy (ART)-naive patients receiving PPIs should receive no more than a 20-mg dose equivalent of omeprazole, which should be taken approximately 12 hours before boosted atazanavir. Co-administration of atazanavir with PPIs is not recommended in treatment-experienced patients.

Patients with hepatitis B virus or hepatitis C virus infections and patients with marked elevations in transaminases before treatment may be at increased risk of further elevations in transaminases or hepatic decompensation.

Atazanavir oral powder contains phenylalanine, which can be harmful to patients with phenylketonuria. Each packet contains 35 mg of phenylalanine.

Metabolism

• Atazanavir is a substrate and inhibitor of cytochrome P (CYP) 3A4 and an inhibitor of CYP1A2, CYP2C9, and uridine diphosphateglucoronosyltransferase (UGT1A1).
• Dosing of atazanavir in patients with hepatic impairment: Atazanavir should be used with
Evotaz once daily with food.
- Atazanavir 400 mg once daily with food (if unboosted atazanavir is used in adolescents, higher doses than those used in adults may be required to achieve target drug concentrations [see Pediatric Use]).

Caution in patients with mild-to-moderate hepatic impairment; consult manufacturer’s prescribing information for dosage adjustment in patients with moderate impairment. Atazanavir should not be used in patients with severe hepatic impairment.
- Dosing of atazanavir in patients with renal impairment: No dose adjustment is required for patients with renal impairment. However, atazanavir should not be given to treatment-experienced patients with end-stage renal disease on hemodialysis.

Antiretroviral-Experienced Patients:
- Atazanavir 300 mg plus ritonavir 100 mg, both once daily with food
- Atazanavir 300 mg plus cobicistat 150 mg, both once daily with food or as co-formulated Evotaz once daily with food

Atazanavir In Combination With Efavirenz (Adults) In Treatment-Naive Patients Only:
- Atazanavir 400 mg plus ritonavir 100 mg plus efavirenz 600 mg, all once daily at separate times.
- Although atazanavir/ritonavir should be taken with food, efavirenz should be taken on an empty stomach, preferably at bedtime. Efavirenz should not be co-administered with atazanavir (with or without ritonavir) in treatment-experienced patients because efavirenz decreases atazanavir exposure.

Atazanavir In Combination With Tenofovir (Adults):
- Atazanavir 300 mg plus ritonavir 100 mg plus tenofovir 300 mg, all once daily with food.
- Atazanavir 300 mg plus cobicistat 150 mg plus tenofovir 300 mg, all once daily with food.
- Only boosted atazanavir should be used in combination with tenofovir because tenofovir decreases atazanavir exposure.

See Cobicistat section for important information about toxicity, drug interactions, and monitoring of patients who receive cobicistat and the combination of cobicistat and tenofovir.
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

• **Metabolism:** Atazanavir is both a substrate and an inhibitor of the cytochrome P (CYP) 3A4 enzyme system and has significant interactions with drugs highly dependent on CYP3A4 for metabolism. Atazanavir also competitively inhibits CYP1A2 and CYP2C9. **Atazanavir is a weak inhibitor of CYP2C8,** There is potential for multiple drug interactions with atazanavir. Atazanavir inhibits the glucuronidation enzyme uridine diphosphate glucuronosyltransferase (UGT1A1). A patient’s medication profile should be carefully reviewed for potential drug interactions with atazanavir before the drug is administered.

• **Nucleoside reverse transcriptase inhibitors (NRTIs):** Tenofovir disoproxil fumarate (tenofovir) decreases atazanavir plasma concentrations. Only ritonavir-boosted atazanavir should be used in combination with tenofovir.

• **Non-nucleoside reverse transcriptase inhibitors:** Efavirenz, etravirine, and nevirapine decrease atazanavir plasma concentrations significantly. Nevirapine and etravirine should not be co-administered to patients receiving atazanavir (with or without ritonavir). Efavirenz should not be co-administered with atazanavir in treatment-experienced patients, but may be used in combination with atazanavir 400 mg plus ritonavir boosting in treatment-naive adults.

• **Integrase Inhibitors:** Atazanavir is an inhibitor of UGT1A1 and may increase plasma concentrations of raltegravir. This interaction may not be clinically significant.

• **Absorption:** Atazanavir absorption is dependent on low gastric pH. When atazanavir is administered with medications that alter gastric pH, dosage adjustment is indicated. No information is available on dosing atazanavir in children when the drug is co-administered with medications that alter gastric pH.

• Initiation of cobicistat, a CYP3A inhibitor, in patients receiving medications metabolized by CYP3A, or initiation of medications metabolized by CYP3A in patients already receiving cobicistat, may increase plasma concentration of these medications, which may increase the risk of clinically significant adverse reactions (including life-threatening or fatal reactions) associated with the concomitant medications. Co-administration of cobicistat with atazanavir in combination with CYP3A inducers may lead to lower exposure of cobicistat and atazanavir and loss of efficacy of atazanavir and possible resistance. Co-administration of cobicistat and atazanavir with some antiretroviral (ARV) agents (e.g., with etravirine, with efavirenz in treatment-experienced patients, with another ARV that requires pharmacokinetic (PK) enhancement, such as another protease inhibitor [PI] or elvitegravir) may result in decreased plasma concentrations of that agent, leading to loss of therapeutic effect and development of resistance.

Guidelines for dosing atazanavir with antacids, H2 receptor antagonists, and proton-pump inhibitors (PPIs) in adults are as follows:

• **Antacids:** Atazanavir concentrations are decreased when the drug is co-administered with antacids and buffered medications (including buffered didanosine formulations); therefore, atazanavir should be administered 2 hours before or 1 hour after these medications.

• **H2-receptor antagonists (unboosted atazanavir in treatment-naive patients):** H2 receptor antagonists are expected to decrease atazanavir concentrations by interfering with absorption of the ARV agent. Atazanavir 400 mg should be administered at least 2 hours before or at least 10 hours after a dose of the H2 receptor antagonist (a single dose of an H2 receptor antagonist should not exceed a dose comparable to famotidine 20 mg; a total daily dose should not exceed a dose comparable to famotidine 40 mg).

• **H2-receptor antagonists (boosted atazanavir in treatment-naive or treatment-experienced patients):** H2 receptor antagonists are expected to decrease atazanavir concentrations by interfering with absorption of the ARV. Dose recommendations for H2 receptor antagonists are either a ≤40-mg dose equivalent of famotidine twice daily for treatment-naive patients or a ≤20-mg dose equivalent of famotidine twice daily for treatment-experienced patients. Boosted atazanavir (atazanavir 300 mg plus ritonavir 100 mg)
should be administered simultaneously with and/or ≥10 hours after the dose of H2 receptor antagonist.

- **H2-receptor antagonists (boosted atazanavir with tenofovir):** Treatment-experienced patients using both tenofovir and H2-receptor antagonists should be given an increased dose of atazanavir (atazanavir 400 mg plus ritonavir 100 mg plus tenofovir 300 mg).

- **PPIs:** Co-administration of PPIs with atazanavir is expected to substantially decrease atazanavir plasma concentrations and decrease its therapeutic effect. Dose recommendations for therapy-naive patients are ≤20-mg dose equivalent of omeprazole taken approximately 12 hours before boosted atazanavir (atazanavir 300 mg plus ritonavir 100 mg). Co-administration of atazanavir with PPIs is not recommended in treatment-experienced patients.

**Major Toxicities**

- **More common:** Indirect hyperbilirubinemia that can result in jaundice or icterus, but is not a marker of hepatic toxicity. Headache, fever, arthralgia, depression, insomnia, dizziness, nausea, vomiting, diarrhea, and paresthesia.

- **Less common:** Prolongation of PR interval of electrocardiogram (ECG). Abnormalities in atroventricular (AV) conduction generally limited to first-degree AV block, but with rare reports of second-degree AV block. Rash, generally mild to moderate, but in rare cases includes life-threatening Stevens-Johnson syndrome. Fat maldistribution and lipid abnormalities may be less common than with other PIs. However, the addition of ritonavir to atazanavir is associated with lipid abnormalities but to a lesser extent than with other boosted PIs.

- **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, and elevation in serum transaminases. Nephrolithiasis. Hepatotoxicity (patients with hepatitis B or hepatitis C are at increased risk).

**Resistance**

**Pediatric Use**

**Approval**

Atazanavir is Food and Drug Administration (FDA)-approved for use in infants (aged >3 months and weight ≥10 kg), children, and adolescents.

**Pharmacokinetics and Dosing**

**Oral Capsule**

The results of the IMPAACT/PACTG 1020A trial in children and adolescents indicate that, in the absence of ritonavir boosting, atazanavir can achieve protocol-defined PK targets, but only when used at higher doses of atazanavir (on a mg/kg body weight or mg/m² body surface area basis) than doses currently recommended in adults. In IMPAACT/PACTG 1020A, children aged >6 to <13 years required atazanavir dosing of 520 mg/m² per day of atazanavir capsule formulation to achieve PK targets. Unboosted atazanavir at this dose was well tolerated in those aged <13 years who were able to swallow capsules. Doses required for older adolescents were greater than the adult approved dose of 400 mg atazanavir given without ritonavir boosting once daily: adolescents aged >13 years required atazanavir dosing of 620 mg/m² per day. In this study, the areas under the curve (AUCs) for the unboosted arms were similar to the ritonavir-boosted atazanavir groups but the maximum plasma concentration (C_max) was higher and minimum plasma concentration (C_min) lower for the unboosted arms. Median doses of atazanavir in mg/m² both with and without ritonavir boosting from IMPAACT/PACTG 1020A are outlined in the following table. When dosing unboosted atazanavir in pediatric patients, therapeutic drug monitoring (TDM) is recommended to ensure that adequate atazanavir
plasma concentrations have been achieved. A minimum target trough concentration for atazanavir is 150 ng/mL.\textsuperscript{4} Higher target trough concentrations may be required in PI-experienced patients.

### Summary of Atazanavir Dosing Information Obtained from IMPAACT/PACTG 1020A\textsuperscript{2}

<table>
<thead>

</tbody>
</table>

\textsuperscript{a} Dose satisfied protocol-defined AUC/PK parameters and met all acceptable safety targets. These doses differ from those recommended by the manufacturer. TDM was used to determine patient-specific dosing in this trial.

In the report of the P1020A data, atazanavir satisfied PK criteria at a dose of 205 mg/m\textsuperscript{2} in pediatric subjects when dosed with ritonavir.\textsuperscript{1} However, given the available atazanavir capsule dose strengths, it is not possible to administer the exact mg dose equivalent to the body surface area-based dose. A study of a model-based approach using atazanavir concentration-time data from 3 adult studies and 1 pediatric study (P1020A) supports the use of the following weight-based atazanavir/ritonavir doses that are listed in the current FDA-approved product label for children aged \( \geq 6 \) to <18 years:

- 150/100 mg (15 to <20 kg)
- 200/100 mg (20 to <40 kg)
- 300/100 mg (\( \geq 40 \) kg)\textsuperscript{5}

The modeling used in the study does not assume 100\% treatment adherence and has been shown to perform better than conventional modeling.\textsuperscript{5} The authors acknowledge that atazanavir/ritonavir at 250/100 mg appeared to be a more appropriate dose than atazanavir/ritonavir at 200/100 mg for the 35 to <40 kg weight group; however, this dose is not achievable with current capsule dose strengths (150, 200, and 300 mg).\textsuperscript{5} Some experts would increase atazanavir to 300 mg at \( \geq 35 \) kg to avoid underdosing, especially when administered with tenofovir.

**Cobicistat as a Pharmacokinetic Enhancer:**

No data on the use of cobicistat are available in pediatric patients.

**Oral Powder:**

The unboosted atazanavir powder cohorts in IMPAACT/PACTG P1020A were closed based on the inability to achieve target exposures. For the IMPAACT/PACTG P1020A trial, AUC targets were established based on exposures in adults in early studies of unboosted atazanavir. For that study, target AUC range was 30,000 to 90,000 ng*hr/mL. Boosted atazanavir powder cohorts in IMPAACT/PACTG P1020A in children ages 3 months to 2 years, using a dose of 310 mg/m\textsuperscript{2} daily, achieved average atazanavir exposures that approached but did not meet protocol targets. Variability in exposures was greater, especially among the very young children in this age range.\textsuperscript{2}

Assessment of the PK, safety, tolerability, and virologic response of atazanavir oral powder for FDA approval was based on data from two open-label, multicenter clinical trials:

- PRINCE I: In pediatric patients aged 3 months to <6 years\textsuperscript{6}
- PRINCE II: In pediatric patients aged 3 months to <11 years\textsuperscript{7}

Sixty-five treated patients from both studies weighing 10 kg to <25 kg were evaluated. All patients in the PRINCE trials were treated with boosted atazanavir. Patients weighing 10 kg to <15 kg received 200 mg
atazanavir and 80 mg ritonavir oral solution, and patients weighing 15 kg to <25 kg received 250 mg atazanavir and 80 mg ritonavir oral solution. Using a modified ITT analysis, overall proportions of ARV-naive and ARV-experienced patients with HIV RNA <50 copies/mL at Week 48 were 66% (27/41) and 58% (14/24), respectively. The median increase from baseline in absolute CD4 T lymphocyte count (percent) at 48 weeks of therapy was 412 cells/mm³ (10.5%) in ARV-naive patients and 228 cells/mm³ (6%) in ARV-experienced patients. No new safety concerns were identified in these trials. The FDA label includes the following PK parameters measured in the PRINCE trials, including mean AUC, for the weight ranges that correspond to the recommended doses:

**Pharmacokinetic Parameters for Atazanavir Powder in Children Aged <6 years (PRINCE I and II)\(^a\) versus Capsules in Young Adults\(^b\) and Adults\(^c\)**

\(^a\) Reyataz Product Information
\(^b\) The young adults were also receiving tenofovir; Kiser, Fletcher et al.\(^d\)
\(^c\) Means are geometric means

While the PK targets were met in these PK studies of atazanavir powder, there were large CV%, especially in the youngest patients.

**Transitioning from Powder to Capsules:**

There is no approved atazanavir powder dose for children who reach a weight ≥25 kg while taking the powder. Atazanavir capsules should be used for the child who swallows pills. Bioavailability is higher for the capsules than for the powder when studied in adults; therefore, a lower mg/kg dose is recommended. Opened capsules have not been studied and so should not be used. For children who reach a weight of 25 kg and who cannot swallow pills, the Panel advises increasing to the experimental dose of 300 mg atazanavir powder plus ritonavir oral solution 80 mg, both once daily with food. The ongoing trial of atazanavir/ritonavir powder, Prince II trial, is evaluating the safety, efficacy, and pharmacokinetics of 300 mg atazanavir powder in children weighing ≥25 kg to <35 kg.

**Toxicity**

Nine percent of patients enrolled in the IMPAACT/PACTG 1020A trial had a bilirubin ≥5.1 times the upper limit of normal.\(^3\) Asymptomatic EKG abnormalities were observed in a small number of patients: Grade 3 QTC prolongation in 1 patient, Grade 2 PR or HR changes in 9 patients, and Grade 3 PR prolongations in 3 patients. No significant changes in serum cholesterol or triglycerides were observed during 48 weeks of therapy in 63 children receiving unboosted atazanavir in combination with 2 NRTIs.\(^2\)

**References**

Darunavir (DRV, Prezista)  (Last updated March 5, 2015; last reviewed March 5, 2015)

**Formulations**

- **Oral suspension:** 100 mg/mL
- **Tablets:** 75 mg, 150 mg, 400 mg, 600 mg, and 800 mg

**Fixed-Dose Combination Tablets:**

*With cobicistat:*

- 800 mg darunavir plus 150 mg cobicistat (Prezcobix)

---

### Dosing Recommendations

**Note:** Darunavir should not be used without a pharmacokinetic (PK) enhancer (boosting agent): ritonavir (children and adults) or cobicistat (adults only).

**Neonate/Infant Dose:**

- Not approved for use in neonates/infants.

**Pediatric Dose:**

**Aged <3 years:**

- **Do not use darunavir in children aged <3 years or weighing ≤10 kg** because of concerns related to seizures and death in infant rats due to immaturity of the blood-brain barrier and liver metabolic pathways.

**Aged ≥3 years:**

- See table below for children, aged ≥3 years, who are antiretroviral **treatment-naive and treatment-experienced** with or without one or more darunavir resistance-associated mutations.

**Aged 3 to <18 Years and Weight >10 kg**

<table>

</tbody>
</table>

### Selected Adverse Events

- Skin rash, including Stevens-Johnson syndrome and erythema multiforme
- Hepatotoxicity
- Diarrhea, nausea
- Headaches
- Possible increased bleeding in patients with hemophilia
- Hyperlipidemia, transaminase elevation, hyperglycemia
- Fat maldistribution

### Special Instructions

- In patients with one or more darunavir-associated mutation(s), darunavir should only be used twice daily. **Darunavir resistance-associated mutations are:** V11I, V32I, L33F, I47V, I50V, I54L, I54M, T74P, L76V, I84V, and L89V.

- Darunavir must be administered with food, which increases area under the curve (AUC) and maximum plasma concentration (C_max) by 30%. Drug exposure is not significantly altered by the calorie and fat content of the meal.

- Darunavir contains a sulfonamide moiety. The potential for cross sensitivity between darunavir and other drugs in the sulfonamide class is unknown. Use darunavir with caution in patients with known sulfonamide allergy.

- Pediatric dosing requires co-administration of tablets with different strengths to achieve the recommended doses depending on weight band. Careful instructions to caregivers when recommending a combination of different-strength tablets is very important. Store darunavir tablets and oral suspension at room temperature (25°C or 77°F). Oral suspension...
should be stored in the original container and shaken well before dosing.

Metabolism

• Cytochrome (CYP) P450 3A4 inhibitor and substrate.

Dosing in Patients with Hepatic Impairment:

• Darunavir is primarily metabolized by the liver. There are no data for dosing adult patients with varying degrees of hepatic impairment; caution should be used when administering darunavir to such patients. Darunavir is not recommended in patients with severe hepatic impairment.

Dosing in Patients with Renal Impairment:

• No dose adjustment is required in patients with moderate renal impairment (creatinine clearance [CrCl] 30–60 mL/min). There are no PK data in patients with severe renal impairment or end-stage renal disease.

Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

• Darunavir is primarily metabolized by cytochrome P (CYP) 3A4. Both ritonavir and cobicistat are inhibitors of CYP3A4, thereby increasing the plasma concentration of darunavir. Potential exists for multiple drug interactions when either ritonavir or cobicistat is used with darunavir. Co-administration of darunavir/ritonavir or darunavir/cobicistat with drugs that are highly dependent on CYP3A clearance creates potential for multiple drug-drug interactions and may be associated with serious and/or life-threatening events or suboptimal efficacy. Co-administration of several drugs, including rifampin, is
contraindicated with ritonavir- or cobicistat-boosted darunavir. Because data are lacking on the plasma concentrations, darunavir/cobicistat should not be used in combination with efavirenz, nevirapine, and etravirine, or other HIV-1 protease inhibitors (including fosamprenavir, saquinavir, or tipranavir). When darunavir/ritonavir was used twice daily in combination with etravirine in 40 HIV-infected patients aged 11 to 20 years, both darunavir and etravirine exposure were lower than that found in adults. When darunavir/ritonavir twice daily was used in combination with tenofovir disoproxil fumarate (tenofovir) in 13 HIV-infected patients aged 13 to 16 years, both tenofovir and darunavir exposures were lower than those found in adults treated with the same combination. No dose adjustment is currently recommended for use of the combination of darunavir/ritonavir with either of these drugs, but caution is advised and therapeutic drug monitoring may be potentially useful.

- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions.

**Major Toxicities**

- **More common:** Diarrhea, nausea, vomiting, abdominal pain, headache, and fatigue.
- **Less common:** Skin rash, including erythema multiforme and Stevens-Johnson syndrome. Fever and elevated hepatic transaminases. Lipid abnormalities. **Crystalluria.**
- **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, and spontaneous bleeding in hemophiliacs. Hepatic dysfunction, particularly in patients with underlying risk factors (such as hepatitis B or hepatitis C virus coinfection, or those with baseline elevation in transaminases).

**Resistance**

**Pediatric Use**

**Approval**

Darunavir co-administered with ritonavir is approved by the Food and Drug Administration (FDA) as a component of combination antiretroviral therapy (cART) in treatment-naïve and treatment-experienced children aged 3 years and older.

**Efficacy**

Data from the randomized, open-label, multicenter pediatric trial, which evaluated darunavir with ritonavir twice daily among 80 treatment-experienced children aged 6 to <18 years, demonstrated that 66% of patients had week 24 plasma HIV RNA <400 copies/mL and 51% had HIV RNA <50 copies/mL. In another international, multisite clinical trial (TMC114-TiDP29-C228) involving treatment-experienced children aged 3 to <6 years, 81% of children (out of 21) had viral load <50 copies/mL at week 48.

**Pharmacokinetics**

**Pharmacokinetics in Younger Children**

Administration of twice-daily darunavir/ritonavir oral suspension in children aged 3 to <6 years and weighing 10 to <20 kg was conducted in 27 children (see above) who experienced failure of their previous cART regimen and had fewer than 3 darunavir resistance mutations on genotypic testing. The darunavir area under the curve [AUC(0–12h)], measured as a percent of the adult AUC value, was 128% overall: 140% in subjects weighing 10 to <15 kg and 122% in subjects weighing 15 to <20 kg.

**Pharmacokinetics in Older Children**

Using darunavir tablets and ritonavir liquid or tablets, initial pediatric pharmacokinetic (PK) evaluation was based upon a Phase II randomized, open-label, multicenter study that enrolled 80 treatment-experienced children...
and adolescents aged 6 to <18 years and weighing ≥20 kg. In Part I of the trial, a weight-adjusted dose of darunavir 9 to 15 mg/kg and ritonavir 1.5 to 2.5 mg/kg twice daily, equivalent to the standard adult dose of darunavir/ritonavir 600/100 mg twice daily, resulted in inadequate drug exposure in the pediatric population studied with 24-hour AUC (AUC$_{24h}$) of 81% and pre-dose concentration (C$_{0h}$) of 91% of the corresponding adult PK parameters. A pediatric dose 20% to 33% higher than the directly scaled adult dose was needed to achieve drug exposure similar to that found in adults and was the dose selected for Part II of the study. The higher dose used for the safety and efficacy evaluation was darunavir 11 to 19 mg/kg and ritonavir 1.5 to 2.5 mg/kg twice daily. This resulted in darunavir AUC$_{24h}$ of 123.276 mcg*h/mL (range 71.850–201.520) and C$_{0h}$ of 3693 ng/mL (range 1842–7191), 102% and 114% of the respective PK values in adults. Doses were given twice daily and were stratified by body weight bands of 20 to <30 kg and 30 to <40 kg. Based on the findings in the safety and efficacy portion of the study, current weight-band doses of twice-daily ritonavir-boosted darunavir for treatment-experienced pediatric patients with weight >20 to <40 kg were selected (see Table A).

### Dosing

**Pharmacokinetic Enhancers**

Darunavir should not be used without a PK enhancer (boosting agent): ritonavir (children and adults) or cobicistat (adults only).

A study in 19 Thai children used ritonavir 100 mg capsule twice daily as the boosting dose with twice-daily darunavir doses of 375 mg (body weight 20 to <30 kg), 450 mg (body weight 30–40 kg), and 600 mg twice daily (body weight ≥40 kg). The darunavir exposures with 100-mg ritonavir twice daily were similar to those obtained in the studies with lower (<100 mg) liquid preparation-based ritonavir doses. The tolerability and PK data from this small study support the higher doses of ritonavir boosting with 100-mg capsule or tablet in children with body weight ≥20 kg, particularly when lower-dose formulations are unavailable or if a child does not tolerate the liquid ritonavir formulation. Data are not available to evaluate the safety and tolerability of using ritonavir 100 mg tablet/capsule formulations in children who weigh less than 20 kg.
The data on the dosing of cobicistat with darunavir are available in adult patients only. Data on a fixed-dose combination of 800/150 mg darunavir/cobicistat once daily showed comparable bioavailability to that obtained with 800/100 mg of darunavir/ritonavir once daily.

**Frequency of Administration**

In February 2013, the FDA approved the use of once-daily darunavir for treatment-naive children and for treatment-experienced children without darunavir resistance-associated mutations (see Table B). To derive once-daily pediatric dosing recommendations for younger pediatric subjects aged 3 to <12 years weighing 10 to <40 kg, population PK modeling and simulation was used. A dedicated pediatric trial evaluating once-daily darunavir with ritonavir dosing in children aged 6 to <12 years was not conducted. No efficacy data have been obtained regarding use of once-daily darunavir with ritonavir in treatment-naive or treatment-experienced children aged <12 years. Therefore, the Panel recommends dosing darunavir with ritonavir twice daily in children aged >3 years and <12 years (see Once-Daily Dosing section). The Panel recommends that once-daily darunavir with ritonavir be used only in treatment-naive and treatment-experienced adolescents aged ≥12 years who do not have darunavir resistance-associated mutations. If darunavir and ritonavir are used once daily in children aged <12 years, the Panel recommends conducting PK (measurement of plasma concentrations) evaluation (see Therapeutic Drug Monitoring) and close monitoring of viral load.

FDA approval was based on results from 2 small pediatric trials: TMC114-C230 evaluating once-daily dosing in treatment-naive adolescents aged 12 to 18 years and weighing ≥40 kg (see below) and the TMC114-C228 sub-trial evaluating once-daily dosing in treatment-experienced children aged 3 to <6 years (see below).

**Table B. FDA-Approved Dosing for Pediatric Patients Aged ≥3 Years and Weight >10 Kg Who Are Antiretroviral Treatment-Naive or Treatment-Experienced With No DRV Resistance-Associated Mutations**

<table>
<thead>

</tbody>
</table>

\(^a\) The dose in children weighing 10 to 15 kg is 35 mg/kg DRV and 7 mg/kg RTV per kg body weight per dose, which is higher than the weight-adjusted dose in children with higher weight.

\(^b\) RTV 80 mg/mL oral solution.

\(^c\) The 350-mg, 385-mg, 455-mg, 490-mg, and 675-mg DRV doses are rounded for suspension-dose convenience.

\(^d\) The 6.8-mL and 8-mL DRV doses can be taken as 2 administrations (3.4 mL and 4 mL, respectively) with the included oral dosing syringe, or as 1 syringe when provided by pharmacy or medical office.

**Key to Acronyms:** DRV = darunavir; RTV = ritonavir

**Once-Daily Administration in Children Aged <12 Years**

As part of the TMC114-C228 trial that evaluated twice-daily dosing in treatment-experienced children aged 3 to <12 years, once-daily dosing of darunavir for 2 weeks with PK evaluation was conducted as a sub-study, after which the participants switched back to the twice-daily regimen. The darunavir/ritonavir dosage for once-daily use in the trial, based on PK simulation (which did not include a relative bioavailability factor),
was 40 mg/kg of darunavir co-administered with approximately 7 mg/kg of ritonavir once daily for children weighing <15 kg, and darunavir/ritonavir 600 mg/100 mg once daily for children weighing ≥15 kg.11,14 The PK data obtained from 10 children aged 3 to 6 years in this sub-study (Table C) were included as part of the population PK modeling and simulation, which proposed the FDA-approved dose for once-daily darunavir with ritonavir in children aged 3 to <12 years.

Once-Daily Administration in Adolescents Age ≥12 Years

A sub-study of once-daily dosing of darunavir 800 mg with ritonavir 100 mg in 12 treatment-naive adolescents (aged 12–17 years and ≥40 kg body weight) demonstrated darunavir exposures similar to those seen in adults treated with once-daily darunavir (see Table D).12 In this study, the proportion of patients with viral load <50 copies/mL and <400 copies/mL at 48 weeks was 83.3% and 91.7%, respectively.13 Interestingly, no relationship was observed between darunavir AUC$_{24}$h and C$_{0h}$ and virologic outcome (HIV RNA <50 copies/mL) in this study. Darunavir exposures were found to be similar to those in adults with once-daily dosing in another study in which a single dose of darunavir 800 mg with ritonavir 100-mg tablets was administered to 24 subjects with median age 19.5 years (14–23 years).15 However, darunavir exposures were slightly below the lower target concentrations in adolescent patients aged 14 to 17 years (n = 7) within the cohort, suggesting the potential need for higher doses in younger adolescents. A single case report suggests the potential therapeutic benefit of virologic suppression using an increased darunavir dose with standard ritonavir booster following therapeutic drug monitoring in a highly treatment-experienced adolescent patient.16

The efficacy of once-daily darunavir has been established within a limited number of studies in small cohorts of adolescents that reported long-term data on virologic and immunologic outcomes.3,17

Formulations

Palatability
Darunavir oral suspension is better tasting than the ritonavir oral solution needed for PK boosting, which is seen as a greater challenge to palatability. In a Phase II initial approval study, 27 of the 80 participants switched from the ritonavir liquid solution to ritonavir 100-mg capsules, which are much easier to tolerate for children who can swallow pills.7 Switching to the higher dose of ritonavir for the palatability of the
boosting drug can be considered if the liquid formulation represents a barrier. **No data are available on the use of cobicistat in pediatric patients.**

**References**

Dosing Recommendations

Pediatric Dose (Aged >6 Months to 18 Years):

- Unboosted fosamprenavir (without ritonavir) is Food and Drug Administration (FDA)-approved for antiretroviral (ARV)-naive children aged 2 to 5 years, but not recommended by The Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel) because of low exposures (see text below).
- Boosted fosamprenavir (with ritonavir) is FDA-approved for ARV-naive infants ≥4 weeks and for treatment-experienced infants ≥6 months; however, the Panel does not recommend use in infants younger than 6 months because of similarly low exposures (see text below). If used in infants as young as 4 weeks, it should only be administered to infants born at 38 weeks’ gestation or greater. Once-daily dosing is not recommended for any pediatric patient.

Aged ≥6 Months to 18 Years:

Twice-Daily Dosage Regimens by Weight for Pediatric Patients ≥6 Months Using Lexiva Oral Suspension with Ritonavir

<table>

</tbody>
</table>

a Not to exceed the adult dose of fosamprenavir 700 mg plus ritonavir 100 mg twice daily.

Selected Adverse Events

- Diarrhea, nausea, vomiting
- Skin rash (Fosamprenavir has a sulfonamide moiety. Stevens-Johnson syndrome and erythema multiforme have been reported.)
- Headache
- Hyperlipidemia, hyperglycemia
- Nephrolithiasis
- Transaminase elevation
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Fosamprenavir tablets with ritonavir should be taken with food. Pediatric patients should take the suspension with food.
- Patients taking antacids or buffered formulations of didanosine should take fosamprenavir at least 1 hour before or after antacid or didanosine use.
- Fosamprenavir contains a sulfonamide moiety. The potential for cross sensitivity between fosamprenavir and other drugs in the sulfonamide class is unknown. Fosamprenavir should be used with caution in patients with sulfonamide allergy.
- Shake oral suspension well before use. Refrigeration is not required.

Metabolism

- The prodrug fosamprenavir is rapidly and almost completely hydrolyzed to amprenavir by cellular phosphatases in the gut as it is absorbed.
Note: When administered with ritonavir, the adult regimen of 700 mg fosamprenavir tablets plus 100 mg ritonavir, both given twice daily, can be used in patients weighing ≥39 kg. Ritonavir pills can be used in patients weighing ≥33 kg.

Adolescent/Adult (Aged >18 Years) Dose:
- Dosing regimen depends on whether the patient is ARV naive or ARV experienced.

ARV-Naive Patients

Boosted with Ritonavir, Twice-Daily Regimen:
- Fosamprenavir 700 mg plus ritonavir 100 mg, both twice daily.

Boosted with Ritonavir, Once-Daily Regimen:
- Fosamprenavir 1400 mg plus ritonavir 100–200 mg, both once daily.

Protease Inhibitor (PI)-Experienced Patients:
- Fosamprenavir 700 mg plus ritonavir 100 mg, both twice daily.
- Note: Once-daily administration of fosamprenavir plus ritonavir is not recommended.

Fosamprenavir in Combination with Efavirenz (Adult):
- Only fosamprenavir boosted with ritonavir should be used in combination with efavirenz.

Twice-Daily Regimen:
- Fosamprenavir 700 mg plus ritonavir 100 mg, both twice daily plus efavirenz 600 mg once daily.

PI-Naive Patients Only, Once-Daily Regimen:
- Fosamprenavir 1400 mg plus ritonavir 300 mg plus efavirenz 600 mg, all once daily.

Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)
- Fosamprenavir has the potential for multiple drug interactions.
- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions with fosamprenavir.

Major Toxicities
- More common: Vomiting, nausea, diarrhea, perioral paresthesia, headache, rash, and lipid abnormalities.
- Less common (more severe): Life-threatening rash, including Stevens-Johnson syndrome, in <1% of

Amprenavir is a cytochrome P450 3A4 (CYP3A4) inhibitor, inducer, and substrate.
- Dosing in patients with hepatic impairment: Dosage adjustment is recommended. Please refer to the package insert.
patients. Fat maldistribution, neutropenia, and elevated serum creatinine kinase levels.

- **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, hemolytic anemia, elevation in serum transaminases, angioedema, and nephrolithiasis.

- **Pediatric specific:** Vomiting was more frequent in children than in adults in clinical trials of fosamprenavir with ritonavir, (20% to 36% vs. 10%, respectively) and in trials of fosamprenavir without ritonavir (60% vs. 16%, respectively). Neutropenia was also more common in children across all the trials (15% vs. 3%, respectively).¹

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

**Pediatric Use**

**Approval**

Fosamprenavir is Food and Drug Administration (FDA)-approved for use in children as young as age 4 weeks, but The Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children (the Panel) recommends use only in children aged 6 months or older. While unboosted fosamprenavir has been approved by the FDA for antiretroviral-naive children aged 2 to 5 years, the Panel does not recommend unboosted fosamprenavir for this—or any other—age group because of low exposures and because unboosted fosamprenavir may select for mutations associated with resistance to darunavir.²

**Efficacy and Pharmacokinetics**

Dosing recommendations for fosamprenavir are based on three pediatric studies that enrolled over 200 children aged 4 weeks to 18 years. In two open-label trials in both treatment-experienced and treatment-naive children aged 2 to 18 years,³fosamprenavir was well-tolerated and effective in suppressing viral load and increasing CD4 T lymphocyte count. However, data were insufficient to support a once-daily dosing regimen of fosamprenavir/ritonavir in children; therefore, once-daily dosing is not recommended for pediatric patients.

**Pharmacokinetics in Infants**

In a study of infants, higher doses of both fosamprenavir and ritonavir were used in treatment-naive infants as young as 4 weeks and in treatment-experienced infants as young as 6 months.⁴ Exposures in those younger than 6 months were much lower than those achieved in older children and adults and comparable to those seen with unboosted fosamprenavir. Given these low exposures, limited data, large dosing volumes, unpleasant taste, and the availability of alternatives for infants and young children, the Panel does not recommend fosamprenavir use in infants younger than 6 months.

### References

### Dosing Recommendations

**Neonate/Infant Dose:**
- Not approved for use in neonates/infants.
- Should not be administered to neonates because of the risks associated with hyperbilirubinemia (kernicterus).

**Pediatric Dose:**
- Not approved for use in children.
- A range of indinavir doses (234–500 mg/m² body surface area) boosted with low-dose ritonavir has been studied in children (see text below).

**Adolescent/Adult Dose:**
- 800 mg indinavir plus 100 or 200 mg ritonavir every 12 hours

### Selected Adverse Events

- Nephrolithiasis
- Gastrointestinal intolerance, nausea
- Hepatitis
- Indirect hyperbilirubinemia
- Hyperlipidemia
- Headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, and hemolytic anemia
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

### Special Instructions

- When given in combination with ritonavir, meal restrictions are not necessary.
- Adequate hydration is required to minimize risk of nephrolithiasis (≥48 oz of fluid daily in adult patients).
- If co-administered with didanosine, give indinavir and didanosine ≥1 hour apart on an empty stomach.
- Indinavir capsules are sensitive to moisture; store at room temperature (59–86°F) in original container with desiccant.

### Metabolism

- Cytochrome P450 3A4 (CYP3A4) inhibitor and substrate
- **Dosing in patients with hepatic impairment:** Decreased dosage should be used in patients with mild-to-moderate hepatic impairment (recommended dose for adults is 600 mg indinavir every 8 hours). No dosing information is available for children with any degree of hepatic impairment or for adults with severe hepatic impairment.
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Metabolism:** CYP3A4 is the major enzyme responsible for metabolism. There is potential for multiple drug interactions.

- Avoid other drugs that cause hyperbilirubinemia, such as atazanavir.

- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions with indinavir.

**Major Toxicities**

- **More common:** Nausea, abdominal pain, headache, metallic taste, dizziness, asymptomatic hyperbilirubinemia (10%), lipid abnormalities, pruritus, and rash. Nephrolithiasis/urolithiasis with indinavir crystal deposits.

- **Less common (more severe):** Fat maldistribution.

- **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of preexisting diabetes mellitus, spontaneous bleeding in hemophiliacs, acute hemolytic anemia, and hepatitis (life-threatening in rare cases).

- **Pediatric specific:** The cumulative frequency of nephrolithiasis is higher in children (29%) than in adults (12.4%).

**Resistance**

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

**Pediatric Use**

**Approval**

Indinavir has not been approved by the Food and Drug Administration (FDA) for use in the pediatric population. Although indinavir was one of the first protease inhibitors to be studied in children, its use in pediatrics has never been common and is currently very rare.\(^1\)

**Dosing**

Both unboosted and ritonavir-boosted indinavir have been studied in HIV-infected children. Data in children indicate that an unboosted indinavir dose of 500 to 600 mg/m\(^2\) body surface area given every 8 hours results in peak blood concentrations and area under the curve slightly higher than those in adults but considerably lower trough concentrations. A significant proportion of children have trough indinavir concentrations less than the 0.1 mg/L value associated with virologic efficacy in adults.\(^2\)\(^-\)\(^5\) Studies in small groups of children of a range of ritonavir-boosted indinavir doses have shown that indinavir 500 mg/m\(^2\) body surface area plus ritonavir 100 mg/m\(^2\) body surface area twice daily is probably too high,\(^4\) that indinavir 234 to 250 mg/m\(^2\) body surface area plus low-dose ritonavir twice daily is too low,\(^7\)\(^,\)\(^8\) and that indinavir 400 mg/m\(^2\) body surface area plus ritonavir 100 to 125 mg/m\(^2\) body surface area twice daily results in exposures approximating those seen with 800 mg indinavir/100 mg ritonavir twice daily in adults, albeit with considerable inter-individual variability and high rates of toxicity.\(^8\)\(^-\)\(^10\)

**Toxicity**

The cumulative frequency of nephrolithiasis is substantially higher in children (29%) than in adults (12.4%, range across clinical trials 4.7%–34.4%).\(^11\) This is likely due to the difficulty in maintaining adequate hydration in children. Finally, a large analysis of more than 2,000 HIV-infected children from PACTG 219
demonstrated a hazard ratio of 1.7 for risk of renal dysfunction in children receiving combination antiretroviral therapy with indinavir.12

References

Dosing Recommendations

Neonatal Dose (<14 Days):
- No data on appropriate dose or safety in this age group. Do not administer to neonates before a post-menstrual age of 42 weeks and a postnatal age of at least 14 days because of potential toxicities.

Dosing for Individuals not Receiving Concomitant Nevirapine, Efavirenz, Fosamprenavir, or Nelfinavir

Infant Dose (14 Days–12 Months):
- Once-daily dosing is not recommended.
- 300 mg/75 mg lopinavir/ritonavir per m² of body surface area twice daily (approximates 16 mg/4 mg lopinavir/ritonavir per kg body weight twice daily). Note: This dose in infants aged <12 months is associated with lower lopinavir trough levels than those found in adults; lopinavir dosing should be adjusted for growth at frequent intervals (see text below). Also see text for transitioning infants to lower mg per m² dose.

Pediatric Dose (>12 Months to 18 Years):
- Once-daily dosing is not recommended.
- 300 mg/75 mg lopinavir/ritonavir per m² of body surface area per dose twice daily (maximum dose 400 mg/100 mg lopinavir/ritonavir twice daily except as noted below). For patients with body weight <15 kg, this approximates 13 mg/3.25 mg lopinavir/ritonavir per kg body weight twice daily; and for patients with body weight ≥15 to 45 kg this dose approximates 11 mg/2.75 mg lopinavir/ritonavir per kg body weight twice daily. This dose is routinely used by many clinicians and is the preferred dose for treatment-experienced patients with possible decreased lopinavir susceptibility (see text below).

Selected Adverse Events

- Gastrointestinal intolerance, nausea, vomiting, diarrhea, taste alteration
- Asthenia
- Hyperlipidemia, especially hypertriglyceridermia
- Elevated transaminases
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding in patients with hemophilia
- PR interval prolongation
- QT interval prolongation and torsades de pointes
- Risk of toxicity—including life-threatening cardiotoxicity—is increased in premature infants (see Major Toxicities below).

Special Instructions

- Lopinavir/ritonavir tablets can be administered without regard to food; administration with or after meals may enhance gastrointestinal tolerability.
- Lopinavir/ritonavir tablets must be swallowed whole. Do not crush or split tablets.
- Lopinavir/ritonavir oral solution should be administered with food because a high-fat meal increases absorption.
- The poor palatability of lopinavir/ritonavir oral solution is difficult to mask with flavorings or foods (see Pediatric Use).
- Lopinavir/ritonavir oral solution can be kept at room temperature up to 77°F (25°C) if used within 2 months. If kept refrigerated (2° to 8°C or 36° to 46°F) lopinavir/ritonavir oral solution remains stable until the expiration
• 230 mg/57.5 mg lopinavir/ritonavir per m² of body surface area per dose twice daily can be used in antiretroviral (ARV)-naïve patients aged >1 year. For patients <15 kg, this dose approximates 12 mg/3 mg lopinavir/ritonavir per kg body weight given twice daily and for patients ≥15 kg to 40 kg, this dose approximates 10 mg/2.5 mg lopinavir/ritonavir per kg body weight given twice daily.

Weight-Band Dosing for 100 mg/25 mg Lopinavir/Ritonavir Pediatric Tablets for Children/Adolescents

<table>

</tr>
</tbody>
</table>

⁴ Four of the 100 mg/25 mg lopinavir/ritonavir tablets can be substituted by 2 tablets each containing 200 mg/50 mg lopinavir/ritonavir in children capable of swallowing a larger tablet.

⁵ In patients receiving concomitant nevirapine, efavirenz, fosamprenavir, or nelfinavir, for body weight >45 kg, the Food and Drug Administration (FDA)-approved adult dose is 500 mg/125 mg lopinavir/ritonavir twice daily, given as a combination of 2 tablets of 200/50 mg lopinavir/ritonavir and 1 tablet of 100 mg/25 mg lopinavir/ritonavir. Alternatively, 3 tablets of 200/50 mg lopinavir/ritonavir can be used for ease of dosing.

Adult Dose (>18 Years):

- 800 mg/200 mg lopinavir/ritonavir once daily, or
- 400 mg/100 mg lopinavir/ritonavir twice daily.
- Do not use once-daily dosing in children or adolescents, or in patients receiving concomitant therapy with nevirapine, efavirenz, fosamprenavir, or nelfinavir, or in patients with three or more lopinavir-associated mutations (see Special Instructions for list).

- Once-daily dosing is not recommended because of considerable variability in plasma concentrations in children aged <18 years and higher incidence of diarrhea.

- Use of lopinavir/ritonavir once daily is specifically contraindicated if three or more of the following lopinavir resistance-associated substitutions are present—L10F/I/R/V, K20M/N/R, L24I, L33F, M36I, I47V, G48V, I54L/T/V, V82A/C/F/S/T, and I84V—because higher lopinavir trough concentrations may be required to suppress resistant virus.

Metabolism

- Cytochrome P (CYP) 3A4 inhibitor and substrate.
- Dosing of lopinavir/ritonavir in patients with hepatic impairment: Lopinavir/ritonavir is primarily metabolized by the liver. Caution should be used when administering lopinavir to patients with hepatic impairment. No dosing information is currently available for children or adults with hepatic insufficiency.
- In the co-formulation of lopinavir/ritonavir, the ritonavir acts as a pharmacokinetic enhancer, not as an ARV agent. It does this by inhibiting the metabolism of lopinavir and increasing lopinavir plasma concentrations.
In Patients with Three or more Lopinavir-Associated Mutations (see Special Instructions for list):

- 400 mg/100 mg lopinavir/ritonavir twice daily.

Dosing for Individuals Receiving Concomitant Nevirapine, Efavirenz, Fosamprenavir, or Nelfinavir:

**Note:** These drugs induce lopinavir metabolism and reduce lopinavir plasma levels; increased lopinavir/ritonavir dosing is required with concomitant administration of these drugs.

- Once-daily dosing should not be used.

**Pediatric Dose (>12 Months to 18 Years):**

- 300 mg/75 mg lopinavir/ritonavir per m² of body surface area per dose twice daily. See table for weight-band dosing when using tablets.

**Adult Dose (>18 Years):**

- FDA-approved dose is 500 mg/125 mg lopinavir/ritonavir twice daily, given as a combination of 2 tablets of 200/50 mg lopinavir/ritonavir and 1 tablet of 100 mg/25 mg lopinavir/ritonavir. Alternatively, 3 tablets of 200/50 mg lopinavir/ritonavir can be used for ease of dosing. Once-daily dosing should not be used.

**Lopinavir/Ritonavir in Combination with Saquinavir Hard-Gel Capsules (Invirase) or in Combination with Maraviroc:**

- Saquinavir and maraviroc doses may need modification (see sections on SQV and MVC).

**Drug Interactions** (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- *Metabolism:* CYP450 3A4 (CYP3A4) is the major enzyme responsible for metabolism. There is potential for multiple drug interactions.

Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions with lopinavir/ritonavir. In patients treated with lopinavir/ritonavir, fluticasone (a commonly used inhaled and intranasal steroid) should be avoided and an alternative used.

**Major Toxicities**

- *More common:* Diarrhea, headache, asthenia, nausea and vomiting, rash, and hyperlipidemia, especially hypertriglyceridemia.¹ possibly more pronounced in girls than boys.²

- *Less common (more severe):* Fat maldistribution
• **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of preexisting diabetes mellitus, hemolytic anemia, spontaneous and/or increased bleeding in hemophiliacs, pancreatitis, elevation in serum transaminases, and hepatitis (life-threatening in rare cases). PR interval prolongation. QT interval prolongation and torsades de pointes may occur.

• **Special populations—neonates:** Lopinavir/ritonavir **should not be used** in the immediate postnatal period in premature infants because an increased risk of toxicity in premature infants has been reported. These toxicities in premature infants include transient symptomatic adrenal insufficiency,\(^3\) life-threatening bradyarrhythmias and cardiac dysfunction,\(^4\)-\(^6\) and lactic acidosis, acute renal failure, central nervous system depression, and respiratory depression.\(^6\) These toxicities may be from the drug itself and/or from the inactive ingredients in the oral solution, including propylene glycol 15.3%, and ethanol 42.4%.\(^6\) Transient asymptomatic elevation in 17-hydroxyprogesterone levels has been reported in term newborns treated at birth with lopinavir/ritonavir.\(^3\)

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

**Pediatric Use**

**Approval**

Lopinavir/ritonavir is Food and Drug Administration (FDA)-approved for use in children. Ritonavir acts as a pharmacokinetic (PK) enhancer by inhibiting the metabolism of lopinavir and thereby increasing the plasma concentration of lopinavir.

**Pharmacokinetics**

**General Considerations**

There is some controversy about the dosing of lopinavir/ritonavir in children. Children have lower drug exposure than adults when treated with doses that are directly scaled for body surface area. The directly scaled dose approximation of the adult dose in children is calculated by dividing the adult dose by the usual adult body surface area of 1.73 m\(^2\). For the adult dose of 400/100 mg lopinavir/ritonavir, the appropriate pediatric dose would be approximately 230/57.5 mg lopinavir/ritonavir per m\(^2\). However, younger children have enhanced lopinavir clearance and need higher drug doses to achieve drug exposures similar to those in adults treated with standard doses. To achieve similar C\(_{\text{trough}}\) to that observed in adults, the pediatric dose needs to be increased 30% over the dose that is directly scaled for body surface area. Lopinavir exposures in infants\(^7\)-\(^9\) are compared to those in older children\(^10\) and adults\(^11\) in the table below.
Models suggest that diet, body weight and postnatal age are important factors in lopinavir PK, with improved bioavailability as dietary fat increases over the first year of life and with clearance slowing by age 2.3 years. A study from the UK and Ireland in children ages 5.6 to 12.8 years at the time of lopinavir/ritonavir initiation that compared outcomes in children treated with 230 mg/m²/dose versus 300 mg/m²/dose suggests that the higher doses were associated with improved long-term viral load suppression.

### Pharmacokinetics and Dosing

#### 6 Months to 12 Years (Without Concurrent Nevirapine, Efavirenz, Fosamprenavir, or Nelfinavir)

Lower trough concentrations have been observed in children receiving 230 mg/57.5 mg lopinavir/ritonavir per m² of body surface area when compared to the 300 mg/75 mg lopinavir/ritonavir per m² of body surface area per dose twice-daily dose (see table and Verweel, Burger, 2007). Therefore, some clinicians choose to initiate therapy in children ages 6 months to 12 years using 300 mg/75 mg lopinavir/ritonavir per m² of body surface area per dose twice daily (when given without nevirapine, efavirenz, fosamprenavir, or nelfinavir) rather than the FDA-recommended 230 mg/57.5 mg lopinavir/ritonavir per m² of body surface area per dose twice daily.

For infants receiving 300 mg/75 mg lopinavir/ritonavir per m² of body surface area per dose twice daily, immediate dose reduction at age 12 months is not recommended; many practitioners would allow patients to “grow into” the 230 mg/57.5 mg lopinavir/ritonavir per m² of body surface area per dose twice daily dosage as they gain weight over time. Some would continue the infant dose (300 mg/m² of body surface area per dose twice daily) while on lopinavir/ritonavir liquid formulation.

#### Younger Than 6 Weeks to 6 Months (Without Concurrent Nevirapine, Efavirenz, Fosamprenavir, or Nelfinavir)

The PK of the oral solution at approximately 300 mg/75 mg lopinavir/ritonavir per m² body surface area per dose twice daily was evaluated in infants younger than age 6 weeks and infants ages 6 weeks to 6 months. Even at this higher dose, pre-dose (Cₜ₉₀) levels were highly variable but were lower in infants than in children older than age 6 months and were lowest in the youngest infants ages 6 weeks or younger compared with those ages 6 weeks to 6 months. By age 12 months, lopinavir area under the curve (AUC) was similar to that found in older children. Because infants grow rapidly in the first months of life, it is important to optimize lopinavir dosing by adjusting the dose at frequent intervals. Given the safety of doses as high as 400 mg/m² body surface area in older children and adolescents, some practitioners anticipate rapid infant growth and prescribe doses somewhat higher than the 300 mg/m² body surface area dose to allow for projected growth between clinic appointments.

* Data generated in study cited but not reported in final manuscript. Data in table source: personal communication from Edmund Capparelli, PharmD (April 18, 2012)

**Note:** Values are means; all data shown performed in the absence of non-nucleoside reverse transcriptase inhibitors (NNRTIs).

**Key to Acronyms:** AUC = area under the curve; LPV = lopinavir
In both children and adults the lopinavir C\textsubscript{trough} is reduced by concurrent treatment with non-nucleoside reverse transcriptase inhibitors (NNRTIs) or concomitant fosamprenavir, or nelfinavir. Higher doses of lopinavir are recommended if the drug is given in combination with nevirapine, efavirenz, fosamprenavir, or nelfinavir. In 14 children treated with 230 mg/57.5 mg lopinavir/ritonavir per m\textsuperscript{2} body surface area per dose twice daily plus nevirapine, the mean lopinavir C\textsubscript{trough} was 3.77 ± 3.57 mcg/mL.\textsuperscript{10} Not only are these trough plasma concentrations lower than those found in adults treated with standard doses of lopinavir/ritonavir, but the variability in concentration is much higher in children than in adults.\textsuperscript{10,16} In a study of 15 HIV-infected children 5.7 to 16.3 years treated with the combination of 300 mg/75 mg lopinavir/ritonavir per m\textsuperscript{2} body surface area per dose twice daily plus nevirapine, 14 mg/kg body weight per dose once daily there was a 34-fold inter-individual variation in lopinavir trough concentrations, and 5 of 15 (33%) children had lopinavir 12-hour trough concentrations less than 1.0 mcg/mL, the plasma concentration needed to inhibit wild-type HIV.\textsuperscript{17} A PK study in 20 children ages 10 to 16 years treated with the combination of lopinavir/ritonavir 300 mg/75 mg per m\textsuperscript{2} body surface area twice daily plus efavirenz 14 mg/kg body weight per dose once daily showed only 1 (6.6%) patient with sub-therapeutic lopinavir trough concentrations,\textsuperscript{18} perhaps because of the use of a lower efavirenz dose of approximately 11 mg/kg body weight,\textsuperscript{18} compared with efavirenz 14 mg/kg body weight in the Bergshoeff trial.\textsuperscript{17}

### Dosing

#### Once Daily

Once-daily dosing of lopinavir/ritonavir 800 mg/200 mg administered as a single daily dose is FDA-approved for treatment of HIV infection in therapy-naive adults older than age 18 years. However, once-daily administration cannot be recommended for use in children in the absence of therapeutic drug monitoring (TDM). There is high inter-individual variability in drug exposure and trough plasma concentrations below the therapeutic range for wild-type virus as demonstrated in studies of antiretroviral (ARV)-naive children and adolescents.\textsuperscript{19-22} Compared with the soft-gel formulation of lopinavir/ritonavir, the tablet formulation has lower variability in trough levels\textsuperscript{22,23} but the Panel remains concerned about the long-term effectiveness of once-daily ritonavir-boosted lopinavir in children.

#### Dosing and Its Relation to Efficacy

Lopinavir/ritonavir is effective in treatment-experienced patients with severe immune suppression,\textsuperscript{24,25} although patients with greater prior exposure to ARVs may have slower reductions in viral load to undetectable concentrations\textsuperscript{25,26} and less robust response in CD4 T lymphocyte (CD4) percentage.\textsuperscript{27} Twice daily doses of lopinavir used in this cohort were 230 to 300 mg/m\textsuperscript{2} body surface area in 39% of patients, 300 to 400 mg/m\textsuperscript{2} body surface area in 35%, and greater than 400 mg/m\textsuperscript{2} body surface area per dose in 4%.\textsuperscript{27}

More important than viral resistance to lopinavir is the relationship of the drug exposure (trough plasma concentration measured just before a dose, or C\textsubscript{trough}) to the susceptibility of the HIV-1 isolate (EC\textsubscript{50}). The ratio of C\textsubscript{trough} to EC\textsubscript{50} is called the inhibitory quotient (IQ), and in both adults and children treated with lopinavir/ritonavir, viral load reduction is more closely associated with IQ than with either the C\textsubscript{trough} or EC\textsubscript{50} alone.\textsuperscript{28-30} A study of the practical application of the IQ to guide therapy using higher doses of lopinavir/ritonavir in children and adolescents to reach a target IQ of 15 showed the safety and tolerability of doses of 400 mg/100 mg lopinavir/ritonavir per m\textsuperscript{2} body surface area per dose twice daily (without fosamprenavir, nelfinavir, nevirapine, or efavirenz) and 480 mg/120 mg lopinavir/ritonavir per m\textsuperscript{2} body surface area per dose twice daily (with nevirapine or efavirenz).\textsuperscript{15} Results of a modeling study suggest that standard doses of lopinavir/ritonavir may be inadequate for treatment-experienced children and suggest the potential utility of TDM when lopinavir/ritonavir is used in children previously treated with protease inhibitors.\textsuperscript{31}

### Formulations

#### Palatability

The poor palatability of the lopinavir/ritonavir oral solution can be a significant challenge to medication

---

*Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection*
adherence for some children and families. Numbing of the taste buds with ice chips before or after administration of the solution, masking of the taste by administration with sweet or tangy foods, chocolate syrup, or peanut butter, for example, or by having the pharmacist flavor the solution prior to dispensing, are examples of interventions that may improve tolerability. **Alternative pediatric formulations are currently being developed.**

**Do Not Use Crushed Tablets**

Lopinavir/ritonavir tablets must be swallowed whole. Crushed tablets are slowly and erratically absorbed, and result in significantly reduced AUC, C\(_{\text{max}}\), and \(C_{\text{trough}}\) compared with swallowing the whole tablet. The variability of the reduced exposure with the crushed tablets (5% to 75% reduction in AUC) means that a dose modification cannot be relied on to overcome the reduced absorption. Crushed tablets cannot be recommended for use. In a PK study using a generic adult formulation of lopinavir/ritonavir manufactured in Thailand, 21 of 54 children were administered cut (not crushed) pills and had adequate lopinavir \(C_{\text{trough}}\) measurements.

**Toxicity**

**Weight Gain**

Compared with children treated with NNRTI-based regimens, those treated with lopinavir/ritonavir may have less robust weight gain and smaller increases in CD4 percentage. The poor weight gain associated with lopinavir/ritonavir is not understood, but may be related to aversion to the taste of the liquid formulation or decreased appetite.

**References**

Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection

**Dosing Recommendations**

**Neonate/Infant Dose:**
- Nelfinavir should not be used for treatment in children aged <2 years.

**Pediatric Dose (Aged 2–13 Years):**
- 45–55 mg/kg twice daily

**Adolescent/Adult Dose:**
- 1250 mg (five 250-mg tablets or two 625-mg tablets) twice daily
- Some adolescents require higher doses than adults to achieve equivalent drug exposures. Consider using therapeutic drug monitoring to guide appropriate dosing.

**Selected Adverse Events**
- Diarrhea
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Possible increase in bleeding episodes in patients with hemophilia
- Serum transaminase elevations

**Special Instructions**
- Administer nelfinavir with meal or light snack.
- If co-administered with didanosine, administer nelfinavir 2 hours before or 1 hour after didanosine.
- Patients unable to swallow nelfinavir tablets can dissolve the tablets in a small amount of water. Once tablets are dissolved, patients should mix the cloudy mixture well and consume it immediately. The glass should be rinsed with water and the rinse swallowed to ensure that the entire dose is consumed. Tablets can also be crushed and administered with pudding or other nonacidic foods.

**Metabolism**
- CYP2C19 and 3A4 substrate
- Metabolized to active M8 metabolite
- CYP3A4 inhibitor

**Drug Interactions** (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/

- *Metabolism:* Cytochrome P (CYP) 2C19 and 3A4 substrate. Metabolized to active M8 metabolite. CYP3A4 inhibitor. However, ritonavir boosting does not significantly increase nelfinavir concentrations and co-administration of nelfinavir with ritonavir is not recommended.
- There is potential for multiple drug interactions with nelfinavir.
- Before administering nelfinavir, carefully review a patient’s medication profile for potential drug interactions.
Major Toxicities

- **More common:** Diarrhea (most common), asthenia, abdominal pain, rash, and lipid abnormalities.
- **Less common (more severe):** Exacerbation of chronic liver disease, fat redistribution.
- **Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, and elevations in transaminases.

Resistance

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR](http://hivdb.stanford.edu/DR)).

Pediatric Use

Approval

Nelfinavir is a protease inhibitor (PI) approved for use in combination with 2 nucleoside reverse transcriptase inhibitors in children 2 to 13 years of age. Nelfinavir is not recommended for treatment of children aged <2 years.

Efficacy in Pediatric Clinical Trials

Nelfinavir in combination with other antiretroviral drugs has been extensively studied in HIV-infected children.1-8 In randomized trials of children aged 2 to 13 years receiving nelfinavir as part of triple combination antiretroviral therapy (cART), the proportion of patients with HIV RNA <400 copies/mL through 48 weeks of therapy has been quite variable, ranging from 26% to 69%. The antiviral response to nelfinavir is significantly less in children younger than age 2 years than in older children.6,8,19 In clinical studies, virologic and immunologic response to nelfinavir-based therapy has varied according to the patient’s age or prior history of cART, the number of drugs included in the combination regimen, and dose of nelfinavir used.

Pharmacokinetics: Exposure-Response Relationships

The relatively poor ability of nelfinavir to control plasma viremia in infants and children in clinical trials may be related to lower potency compared with other PIs or non-nucleoside reverse transcriptase inhibitors, as well as highly variable drug exposure, metabolism, and poor patient acceptance of available formulations.9-11

Administration of nelfinavir with food increases nelfinavir exposure (area under the curve increased by as much as five fold) and decreases pharmacokinetic (PK) variability relative to the fasted state. Drug exposure may be even more unpredictable in pediatric patients than in adults because of increased clearance of nelfinavir observed in children, and difficulties in taking nelfinavir with sufficient food to improve bioavailability. A pediatric powder formulation, no longer available, was poorly tolerated when mixed with food or formula. In the PENTA-7 trial, 35% (7 of 20) of infants started on powder at initiation of therapy were switched from the powder to crushed tablets because of difficulty administering the oral formulation to the infants.1 A slurry made by dissolving nelfinavir tablets in water or other liquids can be administered to children who are unable to swallow tablets. The bioavailability of dissolved nelfinavir tablets is comparable to that of tablets swallowed whole.12

Nelfinavir is metabolized by multiple CYP-450 enzymes including CYP3A4 and CYP2C19. M8, the major oxidative metabolite, has in vitro antiviral activity comparable to the parent drug. The variability of drug exposure at any given dose is much higher for children than for adults,13 which has been attributed—at least in part—to differences in the diets of children and adults. Two population PK studies of nelfinavir and its active metabolite, M8, describe the large intersubject variability observed in children.14,15 Analysis of data from PACTG 377 and PACTG 366 showed that CYP2C19 genotypes altered nelfinavir PKs and the virologic
responses to combination therapy in HIV-1-infected children. These findings suggest that CYP2C19 genotypes are important determinants of nelfinavir PKs and virologic response in HIV-1-infected children.9

Several studies have demonstrated a correlation between nelfinavir trough concentrations and virologic response. In both children and adults, an increased risk of virologic failure was associated with low nelfinavir drug exposure, particularly with a nelfinavir minimum plasma concentration (C_min) <1.0 mcg/mL.16-18

In a study of 32 children treated with nelfinavir 90 mg/kg/day divided into 2 or 3 doses a day, 80% of children with morning trough nelfinavir plasma concentration >0.8 mcg/mL had Week 48 HIV RNA concentrations <50 copies/mL, compared with only 29% of those with morning trough <0.8 mcg/mL.22 It is of note that the median age of the group with C_trough <0.8 mcg/mL was 3.8 years, while the median age of the group with C_trough >0.8 mcg/mL was 8.3 years.22 Therapeutic drug monitoring (TDM) of nelfinavir plasma concentrations, with appropriate adjustments for low drug exposure, results in improved outcome in adults treated with nelfinavir.16,23 Similarly, better virologic responses were demonstrated in two pediatric trials in which TDM was used to guide dosing;15,24 doses higher than those recommended in adults may be required in some patients. Infants have even lower drug exposures and higher variability in plasma concentrations than children weighing <25 kg; the presence of lower peak drug concentrations and higher apparent oral clearance suggests that both poor absorption and more rapid metabolism may be contributing factors.20,22 Given the higher variability of nelfinavir plasma concentrations in infants and children, nelfinavir is not recommended for use in children younger than age 2 years.

**Formulations**
- Hard-Gel Capsules: 200 mg
- Film-Coated Tablets: 500 mg

**Dosing Recommendations**

**Neonate/Infant Dose:**
- Not approved for use in neonates/infants.

**Pediatric Dose:**
- Not approved for use in children.

**Investigational Doses in Treatment-Experienced Children:**
- Saquinavir must be boosted with ritonavir.

**Aged <2 Years:**
- No dose has been determined.

**Aged ≥2 Years (Conditional Dosing Based on Limited Data; See Text):**

<table>
<thead>
<tr>
<th>Weight (kg)</th>
<th>Dose Saquinavir plus Ritonavir</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 to &lt;15 kg</td>
<td>saquinavir 50 mg/kg plus ritonavir 3 mg/kg, both twice daily</td>
</tr>
<tr>
<td>15 to 40 kg</td>
<td>saquinavir 50 mg/kg plus ritonavir 2.5 mg/kg, both twice daily</td>
</tr>
<tr>
<td>≥40 kg</td>
<td>saquinavir 50 mg/kg plus ritonavir 100 mg, both twice daily</td>
</tr>
</tbody>
</table>

**Aged ≥7 Years in Combination with Lopinavir/Ritonavir for Salvage Therapy (Conditional Dosing Based On Limited Data, See Text):**
- Saquinavir 750 mg/m^2^ (max 1600 mg) and saquinavir 50 mg/kg each have been used in combination with lopinavir/ritonavir, both twice daily.

**Adolescent (Aged ≥16 years)/Adult Dose:**
- Saquinavir should only be used in combination with ritonavir or ritonavir-boosted lopinavir (never unboosted).
- Saquinavir 1000 mg + ritonavir 100 mg, both twice daily
- Saquinavir 1000 mg + lopinavir/ritonavir 400/100 mg, both twice daily

**Selected Adverse Events**
- Gastrointestinal intolerance, nausea, and diarrhea
- Headache
- Elevated transaminases
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Increased bleeding episodes in patients with hemophilia
- PR interval prolongation, QT interval prolongation, and ventricular tachycardia (torsades de pointes) have been reported.

**Special Instructions**
- Administer within 2 hours after a full meal.
- Sun exposure can cause photosensitivity reactions; advise patients to use sunscreen or protective clothing.
- Pre-therapy electrocardiogram is recommended and saquinavir is contraindicated in patients with a prolonged QT interval.

**Metabolism**
- Cytochrome P450 3A4 (CYP3A4) substrate and inhibitor, 90% metabolized in the liver.
- Use in patients with hepatic impairment: Use with caution.
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- Saquinavir is both a substrate and inhibitor of the CYP3A4 system. Potential exists for multiple drug interactions. Co-administration of saquinavir is contraindicated with drugs that are highly dependent on CYP3A clearance and for which elevated plasma concentrations are associated with serious and/or life-threatening events.

- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions.

Major Toxicities

- More common: Diarrhea, abdominal discomfort, headache, nausea, paresthesia, skin rash, and lipid abnormalities.

- Less common (more severe): Exacerbation of chronic liver disease, lipodystrophy.

- Rare: New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, pancreatitis, and elevation in serum transaminases. The combination of saquinavir and ritonavir could lead to prolonged PR and/or QT intervals with potential for heart block and ventricular tachycardia (torsades de pointes).

Resistance

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/).

Pediatric Use

Approval

Saquinavir is not Food and Drug Administration-approved for use in children.

Efficacy

Saquinavir has been studied with nucleoside reverse transcriptase inhibitors (NRTIs) and other protease inhibitors in HIV-infected children.\textsuperscript{1-6} Saquinavir/ritonavir and saquinavir/lopinavir/ritonavir regimens were considered for salvage therapy in children prior to the emergence of the new classes of antiretroviral medications.\textsuperscript{1,3-9}

Pharmacokinetics

Studies suggest that saquinavir should not be used without boosting by ritonavir or ritonavir-boosted lopinavir. A pharmacokinetic (PK) analysis of 5 children younger than 2 years and 13 children aged 2 to 5 years using a dose of 50 mg/kg twice daily with ritonavir boosting demonstrated that drug exposure was lower in children younger than 2 years whereas drug exposure was adequate in those aged 2 to 5 years.\textsuperscript{10} For this reason, saquinavir should not be administered to children aged <2 years. In children aged ≥2 years, a dose of 50 mg/kg twice daily (maximum dose = 1000 mg) boosted with ritonavir 3 mg/kg twice daily (patients weighing 5 to <15 kg) or 2.5 mg/kg twice daily (patients weighing 15–40 kg) resulted in area under the curve and steady-state trough plasma concentration (C\textsubscript{trough}) values similar to those in older children\textsuperscript{7,8} and adults.

In a study of 18 children (median age 14.2 years, range 7.7–17.6 years) evaluating the addition of saquinavir (750 mg/m\textsuperscript{2} body surface area every 12 hours, maximum dose 1600 mg) to a regimen containing lopinavir/ritonavir dosed at 400/100 mg/m\textsuperscript{2} body surface area twice daily (for patients not concurrently taking a non-nucleoside reverse transcriptase inhibitor [NNRTI]) or lopinavir/ritonavir 480/120 mg/m\textsuperscript{2} body surface area twice daily for patients concurrently administered an NNRTI, the addition of saquinavir was
well tolerated and did not appear to alter lopinavir PKs. Saquinavir required dose adjustment in four patients (decreased in three, increased in one).9

In a study of 50 Thai children, saquinavir/lopinavir/ritonavir was initiated as second-line therapy based on extensive NRTI resistance (saquinavir was dosed at 50 mg/m² body surface area and lopinavir/ritonavir was dosed at 230/57.5 mg/m² body surface area, all twice daily). After 96 weeks, 74% of the children achieved an undetectable plasma RNA load at <50 copies/mL. Therapeutic drug monitoring was used to establish adequate minimum plasma concentration (Cₘᵢₙ) values and to aid with alterations in drug dosage based upon toxicity. Most Cₘᵢₙ values for saquinavir were above the desired trough value of 0.1 mg/L. The average Cₘᵢₙ throughout 96 weeks for saquinavir was 1.37 mg/L, and when saquinavir doses were adjusted, most were decreased by an average of 21% (8 mg/kg).7,8

Toxicity

In a healthy adult volunteer study, saquinavir/ritonavir use was associated with increases in both QT and PR intervals.11,12 Rare cases of torsades de pointes and complete heart block have been reported in post-marketing surveillance. Saquinavir/ritonavir is not recommended for patients with any of the following conditions: documented congenital or acquired QT prolongation, pretreatment QT interval of >450 milliseconds, refractory hypokalemia or hypomagnesemia, complete atrioventricular block without implanted pacemakers, at risk of complete A V block, or receiving other drugs that prolong QT interval. An electrocardiogram is recommended before initiation of therapy with saquinavir and should be considered during therapy.

References

Tipranavir (TPV, APTIVUS)  (Last updated March 5, 2015; last reviewed March 5, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Oral Solution: 100 mg tipranavir/mL, with 116 International Units (IU) vitamin E/mL
Capsules: 250 mg

Dosing Recommendations

**Note:** Tipranavir must be used with ritonavir boosting. The ritonavir boosting dose used for tipranavir is higher than that used for other protease inhibitors.

**Pediatric Dose (Aged 2 years):**
- Not approved for use in children aged 2 years.

**Pediatric Dose (Aged 2–18 Years):**
- **Note:** Not recommended for treatment-naive patients

**Body Surface Area Dosing:**
- Tipranavir 375 mg/m² plus ritonavir 150 mg/m², both twice daily

**Maximum Dose:**
- Tipranavir 500 mg plus ritonavir 200 mg, both twice daily

**Weight-Based Dosing:**
- Tipranavir 14 mg/kg plus ritonavir 6 mg/kg, both twice daily

**Maximum Dose:**
- Tipranavir 500 mg plus ritonavir 200 mg, both twice daily

**Adult Dose:**
- **Note:** Not recommended for treatment-naive patients
- Tipranavir 500 mg (two 250-mg capsules) plus ritonavir 200 mg, both twice daily

Selected Adverse Events

- Rare cases of fatal and non-fatal intracranial hemorrhage
- Skin rash (more common in children than adults)
- Nausea, vomiting, diarrhea
- Hepatotoxicity
- Hyperlipidemia
- Hyperglycemia
- Fat maldistribution
- Possible increased bleeding episodes in patients with hemophilia

Special Instructions

- Administer tipranavir and ritonavir together with food.
- Tipranavir oral solution contains 116 IU vitamin E/mL, which is significantly higher than the reference daily intake for vitamin E. Patients taking the oral solution should avoid taking any form of supplemental vitamin E that contains more vitamin E than found in a standard multivitamin.
- Tipranavir contains a sulfonamide moiety and should be used with caution in patients with sulfonamide allergy.
- Store tipranavir oral solution at room temperature, 25°C (77°F); do not refrigerate or freeze. Oral solution must be used within 60 days after the bottle is first opened.
- Store unopened bottles of oral tipranavir capsules in a refrigerator at 2°C to 8°C (36°F to 46°F). Once bottle is opened, capsules can be kept at room temperature (maximum of 77°F or 25°C) if used within 60 days.
- Use tipranavir with caution in patients who
may be at increased risk of intracranial hemorrhage, including individuals with brain lesion, head trauma, recent neurosurgery, coagulopathy, hypertension, or alcoholism, or who use anticoagulant or antiplatelet agents (including vitamin E).

• Use of tipranavir is contraindicated in patients with moderate or severe hepatic impairment.

### Metabolism

- Cytochrome P450 3A4 (CYP3A4) inducer and substrate
- Dosing in patients with renal impairment: No dose adjustment required
- Dosing in patients with hepatic impairment: No dose adjustment required for mild hepatic impairment; use contraindicated for moderate-to-severe hepatic impairment.

### Drug Interactions

(see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- Tipranavir (TPV) has the potential for multiple drug interactions. Co-administration of tipranavir/ritonavir (TPV/r) with drugs that are highly dependent on CYP3A for clearance or are potent CYP3A inducers is contraindicated.
- Before tipranavir is administrated, a patient’s medication profile should be carefully reviewed for potential drug interactions.
- Tipranavir should be used with caution in patients who are receiving medications known to increase the risk of bleeding, such as antiplatelet agents, anticoagulants, or high doses of supplemental vitamin E.

### Major Toxicities

**More common:** Diarrhea, nausea, fatigue, headache, rash (more frequent in children than in adults), and vomiting. Elevated transaminases, cholesterol, and triglycerides.

**Less common (more severe):** Lipodystrophy. Hepatotoxicity: clinical hepatitis and hepatic decompensation, including some fatalities. Patients with chronic hepatitis B or hepatitis C coinfection or elevations in transaminases are at increased risk of developing further transaminase elevations or hepatic decompensation (approximately 2.5-fold risk). Epistaxis.

**Rare:** New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of preexisting diabetes mellitus, spontaneous bleeding in hemophiliacs. Increased risk of intracranial hemorrhage. Tipranavir should be used with caution in patients who may be at risk of increased bleeding from trauma, surgery, or other medical conditions.

### Resistance

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

**Pediatric Use**

* Approval and General Considerations

TPV is Food and Drug Administration (FDA)-approved for use in children aged ≥2 years who are treatment-experienced and infected with HIV strains resistant to more than one protease inhibitor (PI).\(^1\) The use of TPV is limited by the high pill burden imposed on patients taking TPV capsules, including the burden of taking a higher dose of boosting ritonavir than is required with other PIs. This increased dose of ritonavir is associated with greater potential for drug interactions and increased toxicity. In addition, TPV is associated with serious adverse events that limit its use to patients with few treatment options. However, TPV is approved for use in children as young as 2 years and is available in a liquid formulation.

**Efficacy**

FDA approval of tipranavir was based on a multicenter, pediatric study of the safety, efficacy, and pharmacokinetics (PKs) of TPV/r in HIV-infected children (PACTG 1051/BI-1182.14).\(^2\) This study enrolled treatment-experienced children (with the exception of three treatment-naive patients) aged 2 to 18 years (median age 11.7 years) with baseline HIV RNA ≥1,500 copies/mL. Children in three age strata were randomized to two different doses of tipranavir/ritonavir: TPV/r 290 mg/115 mg per m\(^2\) body surface area (low dose, 58 patients) or TPV/r 375 mg/150 mg/m\(^2\) body surface area (high dose, 57 patients) twice daily, plus optimized background therapy. At baseline, resistance to all commercially available PIs was present in greater than 50% of patient isolates, and the TPV/r mutation scores increased with age.\(^2\) At 48 weeks, 39.7% of patients receiving the low dose and 45.6% of those receiving the high dose had viral loads <400 copies/mL. The groups did not differ in percentage of patients who achieved viral loads <50 copies/mL. HIV RNA levels <400 copies/mL tended to be seen in a greater proportion of the youngest patients (70%), who had less baseline resistance. TPV treatment was associated with a mean increase in CD4 T lymphocyte count of 100 cells/mm\(^3\) and 59 cells/mm\(^3\) in low- and high-dose groups, respectively, at week 48. Recently, the 5-year long-term follow-up to evaluate safety, efficacy, and tolerability of patients enrolled in PACTG 1051 was reported.\(^3\) At week 288, most children were no longer receiving TPV/r. Reasons for discontinuation included adverse events, virologic failure, and non-adherence. The youngest patients who were stable at week 48 were more likely to still be on treatment after 5 years with continued efficacy.\(^3\)

**Pharmacokinetics**

PK evaluation of the liquid formulation at steady state in children was assessed.\(^4\) In children aged 2 to <12 years, at a dosage of TPV/r 290/115 mg/m\(^2\) body surface area, TPV trough concentrations were consistent with those achieved in adults receiving standard TPV/r 500 mg/200 mg dosing. However, children aged 12 to 18 years required a higher dose (375/150 mg/m\(^2\) body surface area, 30% higher than the directly scaled adult dose) to achieve drug exposure similar to that in adults receiving the standard TPV/r dose. Population PK analysis demonstrated that TPV clearance can be affected by body weight and that volume of distribution can be affected by age.\(^4\) Based on these studies, the final dose of TPV/r 375/150 mg/m\(^2\) body surface area twice daily is recommended.

**Toxicity**

Adverse effects were similar between treatment groups in the multicenter, pediatric study.\(^2\) Twenty-five percent of children experienced a drug-related serious adverse event (AE), and 9% of patients discontinued study drugs because of AEs. The most common AEs were gastrointestinal disturbances; 37% of participants had vomiting and 24% had diarrhea. Moderate or severe laboratory toxicity (primarily increase in gamma glutamyl transpeptidase and creatine phosphokinase) was seen in 11% of children. In the long-term follow-up report for PACTG 1051, incidence of AEs defined as drug-related was 55% to 65% regardless of age at entry, with higher discontinuation rates due to AEs in the older age groups.\(^3\)

Vitamin E is an excipient in the TPV oral solution, with a concentration of 116 IU of vitamin E and 100 mg tipranavir/mL of solution. The recommended dose of TPV (14 mg/kg body weight) results in a vitamin E
dose of 16 IU/kg body weight per day, significantly higher than the reference daily intake for vitamin E (10 IU) and close to the upper limit of tolerability for children. In PACTG 1051, bleeding events were reported more commonly in children receiving TPV oral capsules (14.3%) than in children taking TPV oral solution (5.75%). Overall, the incidence of bleeding episodes (primarily epistaxis) in pediatric patients observed in clinical trials was 7.5%.

References

**Entry and Fusion Inhibitors**

- Enfuvirtide (T-20, Fuzeon)
- Maraviroc (MVC, Selzentry)
Enfuvirtide (T-20, Fuzeon)  (Last updated March 5, 2015; last reviewed March 5, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Lyophilized Powder for Injection:
- 108-mg vial of enfuvirtide. Reconstitution with 1.1 mL sterile water will deliver 90 mg/mL.

Convenience Kit:
- 60 single-use vials of enfuvirtide (90-mg strength), 60 vials of sterile water for injection, 60 reconstitution syringes (3 mL), 60 administration syringes (1 mL), alcohol wipes

Dosing Recommendations

Pediatric/Adolescent Dose (Aged 6–16 Years):

Children Aged <6 Years:
- Not approved for use in children aged <6 years

Children Aged ≥6 Years:
- 2 mg/kg (maximum dose, 90 mg [1 mL]) twice daily injected subcutaneously (SQ) into the upper arm, anterior thigh, or abdomen

Adolescent (Aged >16 Years)/Adult Dose:
- 90 mg (1 mL) twice daily injected SQ into the upper arm, anterior thigh, or abdomen

Selected Adverse Events

- Local injection site reactions (e.g., pain, erythema, induration, nodules and cysts, pruritus, ecchymosis) in up to 98% of patients.
- Increased rate of bacterial pneumonia (unclear association)
- Hypersensitivity reaction (HSR)—symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases. Rechallenge is not recommended.

Special Instructions

- Carefully instruct patient or caregiver in proper technique for drug reconstitution and administration of SQ injections. Enfuvirtide injection instructions are provided with convenience kits.
- Allow reconstituted vial to stand until the powder goes completely into solution, which could take up to 45 minutes. Do not shake.
- Once reconstituted, inject enfuvirtide immediately or keep refrigerated in the original vial until use. Reconstituted enfuvirtide must be used within 24 hours.
- Enfuvirtide must be given SQ; severity of reactions increases if given intramuscularly.
- Give each injection at a site different from the preceding injection site; do not inject into moles, scar tissue, bruises, or the navel. Both the patient/caregiver and health care provider should carefully monitor for signs and symptoms of local infection or cellulitis.
- To minimize local reactions apply ice or heat after injection or gently massage injection site.
to better disperse the dose. There are reports of injection-associated neuralgia and paresthesia when alternative delivery systems, such as needle-free injection devices, are used.

- Advise patients/caregivers of the possibility of a HSR; instruct them to discontinue treatment and seek immediate medical attention if a patient develops signs and symptoms consistent with a HSR.

**Metabolism**
- Catabolism to constituent amino acids.

**Drug Interactions** (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- There are no known significant drug interactions with enfuvirtide.

**Major Toxocities**

- **More common:** Almost all patients (87% to 98%) experience local injection site reactions including pain and discomfort, induration, erythema, nodules and cysts, pruritus, and ecchymosis. Reactions are usually mild to moderate in severity but can be more severe. Average duration of local injection site reaction is 3 to 7 days, but was >7 days in 24% of patients.

- **Less common (more severe):** Increased rate of bacterial pneumonia (unclear association). Pediatric studies have lacked the statistical power to answer questions concerning enfuvirtide use and increased risk of pneumonia.

- **Rare:** Hypersensitivity reactions (HSRs) (<1%) including fever, nausea and vomiting, chills, rigors, hypotension, and elevated liver transaminases; immune-mediated reactions including primary immune complex reaction, respiratory distress, glomerulonephritis, and Guillain-Barre syndrome. Patients experiencing HSRs should seek immediate medical attention. Therapy should not be restarted in patients with signs and symptoms consistent with HSRs.

- **Pediatric specific:** Local site cellulitis requiring antimicrobial therapy (up to 11% in certain subgroups of patients in pediatric studies).²

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)).

**Pediatric Use**

**Approval**

Although enfuvirtide is Food and Drug Administration (FDA)-approved for use in children, it is not commonly used because of its high cost, need for twice-daily subcutaneous (SQ) injections, and high rate of injection site reactions. Use in deep salvage regimens³ has also declined with the availability of integrase inhibitors and other entry inhibitors (such as maraviroc).
**Pharmacokinetics**

A single-dose pharmacokinetic evaluation study of enfuvirtide, given SQ to 14 HIV-infected children aged 4 to 12 years (PACTG 1005), identified that enfuvirtide 60 mg/m² of body surface area per dose resulted in a target trough concentration that approximated the “equivalent” of a 90-mg dose delivered SQ to an adult (1000 mg/mL). In a second pediatric study of 25 children aged 5 to 16 years, a 2-mg/kg dose (maximum 90 mg) of enfuvirtide given twice daily yielded drug concentrations similar to 60 mg/m² of body surface area dose independent of age group, body weight, body surface area, and sexual maturation. The FDA-recommended dose of enfuvirtide for children aged 6 to 16 years is 2 mg/kg (maximum 90 mg) administered SQ twice daily. Further data are needed for dosing in children aged <6 years.

**Efficacy**

The safety and antiretroviral (ARV) activity of twice-daily SQ enfuvirtide administration at 60 mg/m² per dose plus optimized background therapy (OBT) was evaluated over 96 weeks in 14 children aged 4 to 12 years who had failed to achieve viral suppression on multiple prior ARV regimens (PACTG 1005). At 24 weeks 71% of the children had a >1.0 log reduction in viral load; 43% and 21% had HIV RNA levels suppressed to <400 copies/mL and <50 copies/mL, respectively. However, only 36% of children maintained virologic suppression (>1.0 log decrease in HIV RNA) at Week 96. Most children had local injection site reactions. Significant improvements in CD4 T lymphocyte (CD4) percentages and height z scores were observed in children receiving enfuvirtide for 48 and 96 weeks.

**Selected Adverse Events**

- Abdominal pain
- Cough
- Dizziness
- Musculoskeletal symptoms
- Fever
- Rash
- Upper respiratory tract infections
- Hepatotoxicity (which may be preceded by severe rash and/or other signs of systemic allergic reaction)
- Orthostatic hypotension (especially in patients with severe renal insufficiency)

**Special Instructions**

- Conduct testing with HIV tropism assay (see Antiretroviral Drug-Resistance Testing in the main body of the guidelines) before using maraviroc to exclude the presence of CXCR4- using or mixed/dual-tropic HIV. Use maraviroc in patients with only CCR5-tropic virus. Do not use if CXCR4 or mixed/dual-tropic HIV is present.
- Maraviroc can be given without regard to food.
- Instruct patients on how to recognize symptoms of allergic reactions or hepatitis.
- Use caution when administering maraviroc to patients with underlying cardiac disease.

**Metabolism**

- Cytochrome P450 3A4 (CYP3A4) substrate
- **Dosing of maraviroc in patients with hepatic impairment:** Use caution when administering maraviroc to patients with hepatic impairment. Because maraviroc is metabolized by the liver, concentrations may be increased in patients with hepatic impairment.
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Absorption**: Absorption of maraviroc is somewhat reduced with ingestion of a high-fat meal; however, maraviroc can be given with or without food.
- **Metabolism**: Maraviroc is a CYP3A4 and p-glycoprotein (Pgp) substrate and requires dosage adjustments when administered with CYP- or Pgp-modulating medications.
- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions with maraviroc.

Major Toxicities

- **More common**: Cough, fever, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness.
- **Less common (more severe)**: Hepatotoxicity that may be preceded by evidence of a systemic allergic reaction (such as pruritic rash, eosinophilia or elevated immunoglobulin) has been reported. Serious adverse events occurred in fewer than 2% of maraviroc-treated adult patients and included cardiovascular abnormalities (e.g., angina, heart failure, myocardial infarction), hepatic cirrhosis or failure, cholestatic jaundice, viral meningitis, pneumonia, myositis, osteonecrosis, and rhabdomyolysis.

Resistance

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf). Clinical failure may also represent the outgrowth of CXCR4-using (naturally resistant) HIV variants.

Pediatric Use

The pharmacokinetics (PK), safety, and efficacy of maraviroc in patients aged <16 years have not been established. A dose-finding and efficacy study is under way in children ages 2 to 17 years. In this trial, maraviroc dose is based upon body surface area and the presence or absence of a potent CYP3A4 inhibitor in the background regimen. Preliminary PK data are encouraging in those on a potent CYP3A4 inhibitor, but low exposures were seen in those not on a potent CYP3A4 inhibitor. Follow up with participants in this trial continues.

**Dosing Recommendations**

### Neonate/Infant Dose:
- Not approved for use in neonates/infants

### Children Aged <12 Years:
- Not approved for use in children aged <12 years. A clinical trial in treatment-experienced children aged <12 years is under way with an experimental dose of 50 mg in children weighing at least 40 kg.

### Children Aged ≥12 Years and Weighing At Least 40 kg (Treatment-Naive or Treatment-Experienced/Integrase Strand Transfer Inhibitor [INSTI]-Naive):
- 50 mg once daily
- If co-administered with efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin, dolutegravir should be given twice daily at 50 mg per dose.

### Adult Dose

<table>
<thead>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>Treatment-naive or treatment-experienced/INSTI-naive</td>
<td>50 mg once daily</td>
</tr>
<tr>
<td>Treatment-naive or treatment-experienced/INSTI-naive when co-administered with the following potent UGT1A/CYP3A inducers: efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin</td>
<td>50 mg twice daily</td>
</tr>
</tbody>
</table>

**Selected Adverse Events**

- Insomnia
- Headache
- Hypersensitivity reactions including rash, constitutional symptoms and organ dysfunction (including liver injury) have been reported rarely.

### Special Instructions

- May be taken without regard to meals
- Should be taken 2 hours before or 6 hours after taking cation-containing antacids or laxatives, sucralfate, oral iron supplements, oral calcium supplements, or buffered medications
- Poor virologic response to 50 mg dolutegravir twice daily may occur if INSTI-resistance Q148 substitution is present along with 2 or more additional INSTI-resistance mutations: L74I/M, E138A/D/K/T, G140A/S, Y143H/R, E157Q, G163E/K/Q/R/S, or G193E/R.

### Metabolism

- UGT1A1 and cytochrome P450 (CYP) 3A substrate
- Dosing in patients with hepatic impairments: No dose adjustment is necessary in patients with mild or moderate hepatic impairment. Dolutegravir is not recommended in patients with severe hepatic impairment because of lack of data.
- Dolutegravir decreases tubular secretion of creatinine and slightly increases measured serum creatinine, but does not affect glomerular filtration.
- Dosing in patients with renal impairment: No dose adjustment is required in INSTI-naive
patients with mild, moderate, or severe renal impairment or in INSTI-experienced patients with mild or moderate renal impairment.

- Use dolutegravir with caution in INSTI-experienced patients with severe renal impairment (creatinine clearance <30 mL/min) because dolutegravir concentrations will be decreased (the cause of this decrease is unknown).

**Drug Interactions** (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- **Metabolism:** Dolutegravir is a UGT1A1 and CYP 3A substrate and may require dosage adjustments when administered with UGT1A1 or CYP 3A-modulating medications. Because etravirine significantly reduces plasma concentrations of dolutegravir, dolutegravir should not be administered with etravirine without co-administration of atazanavir/ritonavir, darunavir/ritonavir, or lopinavir/ritonavir, which counteracts this effect on dolutegravir concentrations. Dolutegravir should not be administered with nevirapine because of insufficient data.

- Before dolutegravir is administered, a patient’s medication profile should be carefully reviewed for potential drug interactions.

**Major Toxicities**

- **More common:** Insomnia and headache
- **Less common (more severe):** Hypersensitivity reactions characterized by rash, constitutional findings, and sometimes organ dysfunction.

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations ([http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)), and the Stanford University HIV Drug Resistance database offers a discussion of integrase strand transfer inhibitor (INSTI) mutations ([http://hivdb.stanford.edu/DR/](http://hivdb.stanford.edu/DR/)). Poor virologic response to 50 mg dolutegravir twice daily may occur if INSTI-resistance Q148 substitution is present along with two or more additional INSTI-resistance mutations (see table above for list).

**Pediatric Use**

**Approval**

Dolutegravir is Food and Drug Administration (FDA)-approved in combination with other antiretroviral drugs for children aged 12 years and older, weighing at least 40 kg, and who are treatment-naive or treatment-experienced and INSTI-naive.

**Efficacy and Pharmacokinetics**

IMPAACT P1093 is an ongoing open-label trial of HIV-infected children with the plan to enroll down to age 4 weeks. FDA approval of dolutegravir down to age 12 years was based on data from 23 treatment-experienced, INSTI-naive adolescents. Intensive pharmacokinetic (PK) evaluations were performed on the first 10 participants (9 weighing ≥40 kg and receiving 50 mg, 1 weighing 37 kg and receiving 35 mg) and revealed comparable exposures to those seen in adults receiving 50 mg once daily.  

Nine of 10 participants
achieved HIV RNA concentration <400 copies/mL at week 4 (optimal background therapy was added 5 to 10 days after dolutegravir was started). An additional 13 participants were then enrolled for evaluation of long-term outcomes. At 24 weeks and 48 weeks, 70% and 61% had achieved HIV RNA concentration <50 copies/mL, respectively. No safety or tolerability concerns were identified. In addition, children aged ≥6 to <12 years are undergoing PK and longer-term follow up in P1093, using investigational tablets of lower strengths (or the 50-mg tablet if they weigh at least 40 kg). To date, data from 11 participants have demonstrated a favorable safety profile, adequate PK, and virologic efficacy through 24 weeks. An oral pediatric granule formulation will also be studied.

Elvitegravir (EVG, VITEKTA)  (Last updated March 5, 2015; last reviewed March 5, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Tablet: 85 mg and 150 mg

Fixed-Dose Combination Tablet:
Elvitegravir (EVG) + cobicistat (COBI) + emtricitabine (FTC) + tenofovir disoproxil fumarate (TDF) (Stribild):
EVG 150 mg + COBI 150 mg + FTC 200 mg + TDF 300 mg

Dosing Recommendations

Note: EVG should only be used with a pharmacokinetic (PK) enhancer (boosting agent) such as ritonavir as part of a boosted protease inhibitor (PI)-containing regimen, or in combination with cobicistat in Stribild.

Pediatric Dose (Aged <18 Years):
- Not Food and Drug Administration-approved for use in children aged <18 years. EVG (as Vitekta) should not be used in a multi-pill regimen with a boosted PI in this age group (see text). Preliminary data from an ongoing clinical trial suggest the adult formulation of EVG in Stribild may be appropriate for use in youth aged ≥12 years and body weight ≥35 kg.

Adult Dose (Aged ≥18 Years):
- EVG (as Vitekta) must be used in combination with an HIV PI co-administered with ritonavir and another antiretroviral (ARV) drug.

Recommended EVG dosage taken once daily with food (all drugs administered orally)

Selected Adverse Events

- Diarrhea (EVG)
- Stribild-associated adverse events: TDF—renal insufficiency, decreased bone mineral density, flatulence; cobicistat—alteration in tubular secretion of creatinine.

Special Instructions

- Administer with food.
- When used in combination with TDF, monitor estimated creatinine clearance, urine glucose, and urine protein at baseline and every 3 to 6 months while on therapy; in patients at risk of renal impairment, also monitor serum phosphate. Patients with increase in serum creatinine >0.4 mg/dL should be closely monitored for renal safety.
- Screen patients for hepatitis B virus (HBV) infection before use of FTC or TDF. Severe acute exacerbation of HBV can occur when FTC or TDF is discontinued; therefore, monitor hepatic function for several months after therapy with FTC or TDF is stopped.
- Do not use EVG with PIs co-administered with cobicistat (not yet studied), or with other EVG-containing drugs including Stribild. Stribild is not recommended for use with other ARV drugs.

Metabolism

- EVG is metabolized by cytochrome P (CYP) 450 3A4 and is a modest inducer of CYP2C9.
- EVG should only be used with a PK enhancer (boosting agent) such as ritonavir as part of a boosted PI-containing regimen or in combination with cobicistat (in Stribild).
Drug Interactions (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.hiv-druginteractions.org/)

- **Metabolism:** Stribild contains elvitegravir and cobicistat. Elvitegravir is metabolized by cytochrome P (CYP) 450 3A4 and is a modest inducer of CYP2C9. Cobicistat is an inhibitor of CYP3A4 and a weak inhibitor of CYP2D6; in addition, cobicistat inhibits ATP-dependent transporters BCRP and P-glycoprotein and the organic anion transporting polypeptides OAT1B1 and OAT1B3. Potential exists for multiple drug interactions when using cobicistat.

- **Renal elimination:** Drugs that decrease renal function or compete for active tubular secretion could reduce clearance of tenofovir disoproxil fumarate (tenofovir) or emtricitabine. Concomitant use of nephrotoxic drugs should be avoided when using Stribild.

- **Protease inhibitors:** Stribild should not be administered concurrent with products or regimens containing ritonavir because of similar effects of cobicistat and ritonavir on CYP3A metabolism. Cobicistat and ritonavir are not interchangeable, and when administered with either atazanavir or darunavir, may result in different drug interactions when used with other concomitant medications.

- Stribild is not recommended for use with other antiretroviral (ARV) drugs.

**Major Toxicities**

- **More common:** Nausea, diarrhea, and flatulence

- **Less common (more severe):** Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported with nucleoside reverse transcriptase inhibitors (NRTIs) including tenofovir and emtricitabine. Tenofovir caused bone toxicity (osteomalacia and reduced bone density) in animals when given in high doses. Decreases in bone mineral density have been reported in both adults and children taking tenofovir; the clinical significance of these changes is not yet known. Evidence of renal toxicity, including increases in serum creatinine, blood urea nitrogen, glycosuria, proteinuria, phosphaturia, and/or calcium decreases in serum phosphate, has been observed with tenofovir. Numerous case reports of renal tubular dysfunction have been reported in patients receiving tenofovir; patients at increased risk of renal dysfunction should be closely monitored if treated with Stribild.

**Resistance**

The International Antiviral Society-USA (IAS-USA) maintains a list of updated resistance mutations (see https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see http://hivdb.stanford.edu/DR/). There is phenotypic cross-resistance between elvitegravir and raltegravir.¹
Pediatric Use

Approval

Elvitegravir was Food and Drug Administration (FDA)-approved in 2014 as a tablet for use in adults in combination with an HIV protease inhibitor (PI) plus ritonavir and was FDA-approved in 2012 for use in adults as the fixed-dose combination product Stribild, which contains elvitegravir, cobicistat, emtricitabine, and tenofovir. Neither elvitegravir nor Stribild is FDA-approved for use in children aged <18 years.\(^\text{2}\)

Formulations

Elvitegravir is an integrase strand transfer inhibitor that is metabolized rapidly by CYP3A4. Elvitegravir must be used in combination with an HIV PI co-administered with ritonavir and another ARV drug, or in the fixed-dose combination product Stribild,\(^\text{3}\) which contains cobicistat (see below). Cobicistat itself does not have ARV activity, but is a CYP3A4 inhibitor that acts as a pharmacokinetic (PK) enhancer, similar to ritonavir.\(^\text{4}\) Both ritonavir and cobicistat slow elvitegravir metabolism and allow once-daily administration of elvitegravir when used in approved doses and combinations. Note that the dose of elvitegravir is different when used with ritonavir plus atazanavir or lopinavir compared to its use with different PIs plus ritonavir, or compared to its use with cobicistat as a component of Stribild. Complex or unknown mechanisms of drug interactions between cobicistat or ritonavir with elvitegravir and PIs may result in different drug interactions when used with other medications.\(^\text{4}\)

Stribild is FDA-approved as a complete ARV regimen in HIV-1-infected ARV-naive adults aged ≥18 years.\(^\text{3}\) Trials have shown non-inferiority of Stribild to regimens of emtricitabine combined with tenofovir plus ritonavir-boosted atazanavir,\(^\text{5,6}\) or emtricitabine plus tenofovir plus efavirenz.\(^\text{7,8}\) Cobicistat inhibits renal tubular secretion of creatinine, and serum creatinine will often increase soon after initiation of treatment with Stribild. Therefore, creatinine-based calculations of estimated glomerular filtration rate (eGFR) will be altered, even though the actual GFR might be only minimally changed.\(^\text{9}\) Adults who experience a confirmed increase in serum creatinine greater than 0.4 mg/dL from baseline should be closely monitored for renal toxicity by following creatinine for further increases and urinalysis for evidence of proteinuria or glycosuria.\(^\text{9}\) Because tenofovir is included in Stribild and can be associated with renal toxicity, careful periodic evaluation of renal function is warranted. This nephrotoxicity may be more pronounced in patients with pre-existing renal disease.\(^\text{3}\)

Use in Adolescents Aged 12 to 18 Years

A PK study of the adult dose of elvitegravir as Vitekta in 25 youth aged 12 to 18 years showed plasma concentrations similar to those in adults when given in regimens that included darunavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in addition to NRTIs. However, this was a multi-pill regimen and medication adherence was poor during the 48-week treatment phase of the study. Data were insufficient to establish safety and effectiveness of elvitegravir as Vitekta in this age group. Therefore, elvitegravir as Vitekta was not FDA-approved for use in this age group, and is not generally recommended by the Panel.

A PK study of the adult dosage formulation of EVG/COBI/FTC/TDF in 14 HIV-infected youth median age 16 years (range 13–17 years) and weight 57 kg (range 35–80 kg) suggested that elvitegravir drug exposures in adolescents were similar to those in adults.\(^\text{10}\) Preliminary week 24 results in 20 patients from a safety and efficacy study in South Africa, the United States, and Thailand, median age 16 years (range 12–17 years) and weight 55 kg (range 35–82 kg) suggested safety and efficacy similar to that seen in adult trials.\(^\text{11}\) This study is ongoing, with a planned enrollment of 36 participants and duration of 48 weeks to more fully characterize use of EVG/COBI/FTC/TDF in youth aged 12 to 18 years (https://clinicaltrials.gov/ct2/show/NCT01721109).

Use in Children Younger Than 12

Early bioequivalence data of pediatric formulations of both elvitegravir\(^\text{12}\) and cobicistat\(^\text{13}\) support progression to Phase II/III studies in children, which are underway.
References

Dosing Recommendations

Neonate Dose:
- Not approved for use in neonates. **Note:** Metabolism by uridine diphosphate glucotransferase (UGT1A1) is immature in neonates. Neonatal dose is being studied.

Infant/Pediatric Dose

*The weight-based dosing recommendation for the oral suspension is based on approximately 6 mg/kg/dose twice daily.

**Note:** Maximum dose of oral suspension is 5 mL (100 mg) twice daily.

Children Aged 2 to <12 Years:
- <25 kg: Chewable tablet twice daily (maximum of 300 mg twice daily). See table below for chewable tablet dose.
- ≥25 kg: 400-mg film-coated tablet twice daily or chewable tablets twice daily. See table below for chewable tablet dose.

Selected Adverse Events

- Rash, including Stevens-Johnson syndrome, hypersensitivity reaction, and toxic epidermal necrolysis
- Nausea, diarrhea
- Headache
- Insomnia
- Fever
- Creatine phosphokinase elevation, muscle weakness, and rhabdomyolysis

Special Instructions

- Can be given without regard to food
- Chewable tablets may be chewed or swallowed whole.
- **Film-coated tablets, chewable tablets, and oral suspension are not interchangeable.** Chewable tablets and oral suspension have better bioavailability than the film-coated tablets.
- Chewable tablets should be stored in the original package with desiccant to protect from moisture.
- Chewable tablets contain phenylalanine. Therefore, patients with phenylketonuria should make the necessary dietary adjustments.
- Oral suspension is provided with a kit that includes two mixing cups, two dosing syringes, and 60 foil packets. Detailed instructions are provided in Instructions for Use document. Each foil, single-use packet contains 100 mg of raltegravir, which will be suspended in 5 mL of water for final...
### Drug Interactions

(see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- **Metabolism:** The major route of raltegravir elimination is mediated through glucuronidation by uridine diphosphate glucotransferase (UGT1A1).

- Inducers of UGT1A1 such as rifampin and tipranavir may result in reduced plasma concentrations of raltegravir, whereas inhibitors of UGT1A1 such as atazanavir may increase plasma concentrations of raltegravir.

- In adults, an increased dose of raltegravir is recommended when co-administered with rifampin. The appropriate dose adjustment is not known in children.

- Efavirenz and etravirine may decrease raltegravir concentrations.

- Before administration, a patient’s medication profile should be carefully reviewed for potential drug interactions with raltegravir.

- Raltegravir plasma concentrations may be reduced when administered with antacids containing divalent metal cations such as magnesium hydroxide, aluminum hydroxide, or calcium carbonate:
  - Co-administration or administration of raltegravir within 6 hours of aluminum and/or magnesium hydroxide-containing antacids resulted in significantly reduced raltegravir plasma levels and is not recommended.
  - Calcium carbonate decreased raltegravir plasma concentrations to a lesser extent, thus no dose adjustment is recommended with calcium-containing antacids.

### Major Toxicities

- **More common:** Nausea, headache, dizziness, diarrhea, fatigue, itching, and insomnia

- **Less common:** Abdominal pain, vomiting. Patients with chronic active hepatitis B and/or hepatitis C are more likely to experience worsening aspartate aminotransferase (AST), alanine aminotransferase (ALT), or total bilirubin than are patients who are not coinfected.

### Chewable Tablet Dosing Table

*Dosages of chewable tablets in children aged 2 to 12 years:*

<table>
<thead>
<tr>
<th>Body Weight (kg)</th>
<th>Dose</th>
<th>Number of Chewable Tablets</th>
</tr>
</thead>
<tbody>
<tr>
<td>11 to &lt;14</td>
<td>75 mg twice daily</td>
<td>3 x 25 mg twice daily</td>
</tr>
<tr>
<td>14 to &lt;20</td>
<td>100 mg twice daily</td>
<td>1 x 100 mg twice daily</td>

<td>1.5 x 100 mg twice daily</td>
</tr>
<tr>
<td>28 to &lt;40</td>
<td>200 mg twice daily</td>
<td>2 x 100 mg twice daily</td>
</tr>
<tr>
<td>≥40</td>
<td>300 mg twice daily</td>
<td>3 x 100 mg twice daily</td>
</tr>
</tbody>
</table>

- The weight-based dosing recommendation for the chewable tablet is based on approximately 6 mg/kg/dose twice daily.
- The 100-mg chewable tablet can be divided into equal halves.

**Note:** Maximum dose of chewable tablets is 300 mg twice daily.
• **Rare:** Moderate to severe increase in creatine phosphokinase. Myopathy and rhabdomyolysis: Use raltegravir with caution in patients receiving medications associated with these toxicities. Anxiety, depression, and paranoia especially in those with prior history. Rash including Stevens-Johnson syndrome, hypersensitivity reaction, and toxic epidermal necrolysis have been reported. Thrombocytopenia. Cerebellar ataxia. Hepatic failure (with and without associated hypersensitivity) in patients with underlying liver disease and/or concomitant medications.

**Resistance**

The International AIDS Society-USA (IAS-USA) maintains a list of updated resistance mutations (see [https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf](https://www.iasusa.org/sites/default/files/tam/22-3-642.pdf) and the Stanford University HIV Drug Resistance Database offers a discussion of each mutation (see [http://hivdb.stanford.edu/DR](http://hivdb.stanford.edu/DR)).

**Pediatric Use**

**Approval**

Raltegravir is Food and Drug Administration-approved for use in infants and children aged ≥4 weeks and weight ≥3 kg. Current pediatric approval and dosing recommendations are based upon evaluations in 122 patients aged ≥4 weeks to 18 years enrolled in IMPAACT P1066.1

**Efficacy and Pharmacokinetics**

**Children Aged 2 to 18 Years**

IMPAACT P1066 is a Phase I/II open-label multicenter study to evaluate the pharmacokinetic (PK) profile, safety, tolerability, and efficacy of various formulations of raltegravir in combination antiretroviral treatment (cART)-experienced, HIV-infected children and adolescents aged 2 to 18 years in combination with an optimized background cART regimen.1 Subjects receive either the 400-mg, film-coated tablet formulation twice daily (patients aged 6–18 years and weighing at least 25 kg) or the chewable tablet formulation at a dose of 6 mg/kg twice daily (aged 2 to <12 years). In IMPAACT P1066, the initial dose-finding stage includes intensive PK evaluation in various age cohorts (aged 12 to <19 years, 6 to <12 years, 2 to <6 years). Dose selection is based on achieving target PK parameters similar to those seen in adults: PK targets are geometric mean (GM) area under the curve of 14–25 µMxh and GM 12-hour concentration >33 nM. Additional subjects are then enrolled in each age cohort to evaluate long-term efficacy, tolerability, and safety. Ninety-three (97%) subjects completed 24 weeks of treatment with 54% achieving HIV RNA <50 copies/mL with a mean CD4 T lymphocyte (CD4) count (percent [%]) increase of 119 cells/mm³ (3.8%). Ninety-one subjects completed 48 weeks of treatment with 57% achieving HIV RNA <50 copies/mL with a mean CD4 count (percent [%]) increase of 156 cells/mm³ (4.6%).2 In subjects who experienced virologic failure, development of drug resistance and/or poor adherence were contributing factors. The frequency, type, and severity of drug-related adverse reactions through week 48 were comparable to those observed in adult studies. Observed adverse reactions considered drug-related included one patient with grade 3 psychomotor hyperactivity, abnormal behavior, and insomnia; one patient with a grade 2 allergic rash; and one patient with grade 3 ALT and grade 4 AST laboratory elevations. There were no discontinuations due to adverse events and no drug-related deaths.

In 19 HIV-infected children and adolescents with multidrug-resistant virus in the HIV Spanish Pediatric Cohort (CoRiSe), good virologic response and improved CD4 counts were observed when raltegravir was included in an optimized regimen.4 Additional experience from the French expanded access program in treatment-experienced adolescents supports the good virologic and immunologic results observed in IMPAACT P1066.5,6

**Infants/Toddlers Aged at Least 4 Weeks to <2 Years**

IMPAACT P1066 studied 26 infants and toddlers aged 4 weeks to <2 years who were administered the oral suspension in combination with an optimized background regimen. All subjects had received prior antiretrovirals as part of prevention of perinatal transmission and/or treatment of HIV infection, and 69% had baseline plasma HIV-1 RNA exceeding 100,000 copies/mL. Twenty-three (88%) completed 48 weeks of treatment with 44% achieving HIV RNA <50 copies/mL with a mean CD4 count (percent [%]) increase of 492 cells/mm³ (7.8%).1 PK parameters were similar to those achieved for the older cohorts in IMPAACT P1066.
Neonates Aged <4 Weeks

There are no data on the safety and dosing of raltegravir in neonates aged <4 weeks. Raltegravir is metabolized by UGT1A1, the same enzyme responsible for the elimination of bilirubin. UGT enzyme activity is low at birth, and it is likely that raltegravir elimination is prolonged in neonates. In addition, bilirubin and raltegravir may compete for UGT and albumin binding sites.7

Washout PK of raltegravir in neonates born to HIV-infected pregnant women was studied in P1097.8 The neonatal plasma half-life was highly variable, ranging from 9.3 to 184 hours, suggesting potential roles for developmental aspects of neonatal UGT1A1 enzyme activity, redistribution, and/or enterohepatic recirculation of raltegravir. IMPAACT P1110 is a Phase I trial that will evaluate the safety and PK of raltegravir in HIV-1 exposed neonates at high risk of acquiring HIV-1 infection (ClinicalTrials.gov identifier: NCT01780831).

Formulations

The PK of raltegravir was compared in HIV-infected adult patients receiving intact, whole 400-mg tablets and patients who chewed the 400-mg film-coated tablets because of swallowing difficulties. Drug absorption was significantly higher in the group who chewed the tablets, although palatability was rated as poor.9 The raltegravir chewable tablet and oral suspension have higher oral bioavailability than the film-coated tablet based on a comparative study in healthy adult volunteers.10 Inter-patient and intra-patient variability for PK parameters of raltegravir are considerable, especially with the film-coated tablets.1,11 Because of the differences in the bioavailability of the chewable tablets, film-coated tablets, and oral suspension, the dosing recommendations are different and these products are not interchangeable.

**Pharmacokinetic Enhancers**

Cobicistat (COBI, TYBOST)
Ritonavir (RTV, Norvir)
Cobicistat (COBI, TYBOST) (Last updated March 5, 2015; last reviewed March 5, 2015)

For additional information see Drugs@FDA: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm

Formulations

Tablets: 150 mg

Fixed-Dose Combination Tablet:
With emtricitabine plus elvitegravir plus tenofovir: 200 mg emtricitabine plus 300 mg tenofovir disoproxil fumarate (TDF) plus 150 mg elvitegravir plus 150 mg cobicistat (Striballd)
With atazanavir:
300 mg atazanavir plus 150 mg cobicistat (Evotaz)
With darunavir:
800 mg darunavir plus 150 mg cobicistat (Prezcobix)

Dosing Recommendations

Cobicistat is a Pharmacokinetic (PK) Enhancer:
- The only use of cobicistat is in adolescents and adults as a PK enhancer (boosting agent) of selected protease inhibitors (PIs) and the integrase inhibitor elvitegravir. Cobicistat is not interchangeable with ritonavir. See dosing information for specific PIs and elvitegravir that require cobicistat for boosting.

Pediatric Dosing (Aged <18 Years):
- Not approved for use in children aged <18 years

Adolescent (Aged ≥18 Years)/Adult Dosing:
- Cobicistat must either be administered as the combination tablet Stribli, in which case it would not be dosed with any other antiretrovirals (ARVs), or be co-administered with atazanavir or darunavir at the doses listed in the table below, at the same time, or in combination tablets with atazanavir (Evotaz) or darunavir (Prezcobix), with food, and in combination with other ARVs.

<td>Treatment-naive or treatment-experienced with no darunavir-associated resistance mutations</td>
</tr>
</tbody>
</table>

Selected Adverse Events

- When co-administered with TDF, cobicistat may be associated with higher risk of renal tubular adverse events than ritonavir.

Special Instructions

- Cobicistat is not interchangeable with ritonavir.
- Do not administer cobicistat with ritonavir or with drugs containing cobicistat (Stribild).
- Not recommended for use with more than one ARV that requires PK enhancement (e.g., elvitegravir in combination with a PI) because no data are available.
- Use with PIs other than atazanavir 300 mg or darunavir 800 mg administered once daily is not recommended because no data are available on other combinations or doses.
- Patients with a confirmed increase in serum creatinine >0.4 mg/dL from baseline should be closely monitored for renal safety.
- When used in combinations with TDF, monitor serum creatinine, urine protein, and urine glucose at baseline and every 3 to 6 months while on therapy (see Table 13). In patients at risk of renal impairment, also monitor serum phosphate.

Metabolism

- Cytochrome P (CYP) 3A4 and CYP2D6 inhibitor
- Cobicistat inhibits renal tubular secretion of creatinine, increasing the serum creatinine concentration (and estimated glomerular filtration rate) without decreasing actual
glomerular function.

- **Dosing of cobicistat in patients with renal impairment:** Do not use cobicistat with TDF in patients with creatinine clearance below 70 mL/min because of the potential need for dose adjustments of TDF if creatinine clearance drops below 50 mL/min.

### Drug Interactions

*Drug Interactions* (see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and [http://www.hiv-druginteractions.org/](http://www.hiv-druginteractions.org/))

- **Metabolism:** Cobicistat is an inhibitor of CYP3A4 and a weak inhibitor of CYP2D6; in addition, cobicistat inhibits ATP-dependent transporters BCRP and P-glycoprotein and the organic anion transporting polypeptides OAT1B1 and OAT1B3. The potential exists for multiple drug interactions when using cobicistat.
- Before cobicistat is administered, a patient’s medication profile should be carefully reviewed for potential interactions and overlapping toxicities with other drugs.
- Cobicistat and ritonavir are not interchangeable, and administration with either atazanavir or darunavir may result in different drug interactions when used with other concomitant medications.

### Major Toxicities

- **More common:** Nausea, vomiting, diarrhea, abdominal pain, anorexia
- **Less common (more severe):** New onset or worsening of renal impairment when used with TDF. Rhabdomyolysis; increased amylase and lipase.

### Resistance

Not applicable: cobicistat has no antiviral activity. Its sole use is as a PK enhancer of ARVs.

### Pediatric Use

**Approval**

Cobicistat has been approved by the Food and Drug Administration only for use in individuals 18 years or older. It is not approved for use in children.¹

### References

Ritonavir (RTV, Norvir) *(Last updated March 5, 2015; last reviewed March 5, 2015)*

For additional information see Drugs@FDA: [http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm](http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm)

### Formulations

**Oral Solution (Contains 43% Alcohol by Volume):** 80 mg/mL  
**Capsules:** 100 mg  
**Tablets:** 100 mg

### Dosing Recommendations

**Ritonavir as a Pharmacokinetic (PK) Enhancer***:  
- Ritonavir is used as a PK enhancer of other protease inhibitors (PIs) and of an integrase inhibitor (elvitegravir) when elvitegravir is included in a boosted protease-containing regimen. The recommended dose of ritonavir varies and is specific to the drug combination selected. See dosing information for specific PIs and for elvitegravir.

* Ritonavir has antiretroviral activity but is no longer recommended for use as an antiviral agent (see text).

### Selected Adverse Events

- Gastrointestinal (GI) intolerance, nausea, vomiting, diarrhea  
- Paresthesia (circumoral and extremities)  
- Hyperlipidemia, especially hypertriglyceridemia  
- Hepatitis  
- Asthenia  
- Taste perversion  
- Hyperglycemia  
- Fat maldistribution  
- Possible increased bleeding episodes in patients with hemophilia  
- Toxic epidermal necrolysis and Stevens-Johnson syndrome

### Special Instructions

- Administer ritonavir with food to increase absorption and reduce GI adverse effects.  

* Do not administer ritonavir with cobicistat or drugs that contain cobicistat (Stribild).*  

- If ritonavir is prescribed with didanosine, administer the drugs 2 hours apart.  
- Refrigerate ritonavir capsules only if the capsules will not be used within 30 days or cannot be stored below 77°F (25°C). Ritonavir tablets are heat stable.  
- Do not refrigerate ritonavir oral solution; store at room temperature (68°F to 77°F or 20°C to 25°C). Shake the solution well before use.  
- Ritonavir oral solution has limited shelf life; use within 6 months.  
- Patients who have persistent or significant nausea with the capsule may benefit from switching to the tablet. Also, the tablet is smaller than the capsule and thus easier to swallow.
• **To Increase Tolerability of Ritonavir Oral Solution in Children:**
  - Mix solution with milk, chocolate milk, or vanilla or chocolate pudding or ice cream.
  - Before administration, give a child ice chips, a Popsicle, or spoonfuls of partially frozen orange or grape juice concentrate to dull the taste buds, or give peanut butter to coat the mouth.
  - After administration, give a child strong-tasting foods such as maple syrup or cheese.
  - **Check food allergy history** before making these recommendations.

**Drug Interactions**

(see also the Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents and http://www.iasusa.org/sites/default/files/tam/22-3-642.pdf)

- **Metabolism**:
  - Cytochrome P (CYP) 3A4 and CYP2D6 inhibitor; CYP3A4 and CYP1A2 inducer.
  - Dosing of ritonavir in patients with hepatic impairment: Ritonavir is primarily metabolized by the liver. No dosage adjustment is necessary in patients with mild or moderate hepatic impairment. Data are unavailable on ritonavir dosing for adult or pediatric patients with severe hepatic impairment. Use caution when administering ritonavir to patients with moderate-to-severe hepatic impairment.

**Drug Interactions**

- **Metabolism**: Ritonavir is extensively metabolized by and is one of the most potent inhibitors of hepatic cytochrome P450 3A (CYP3A). There is potential for multiple drug interactions with ritonavir.
- Before ritonavir is administered, a patient’s medication profile should be carefully reviewed for potential interactions with ritonavir and overlapping toxicities with other drugs.
- Ritonavir and cobicistat are not interchangeable and may result in different drug interactions.
- Avoid concomitant use of intranasal or inhaled fluticasone because of reports of adrenal insufficiency.
  - Use caution when prescribing ritonavir with other inhaled steroids; limited data suggest that beclomethasone may be a suitable alternative to fluticasone when an inhaled/intranasal corticosteroid is required for a patient who is taking ritonavir.

**Major Toxicities**

- **More common**: Nausea, vomiting, diarrhea, headache, abdominal pain, anorexia, circumoral paresthesia, lipid abnormalities
- **Less common (more severe)**: Exacerbation of chronic liver disease, fat maldistribution
- **Rare**: New-onset diabetes mellitus, hyperglycemia, ketoacidosis, exacerbation of pre-existing diabetes mellitus, spontaneous bleeding in hemophiliacs, pancreatitis, and hepatitis (life-threatening in rare cases). Allergic reactions, including bronchospasm, urticaria, and angioedema. Toxic epidermal necrolysis and Stevens-Johnson syndrome have occurred.
Resistance

Resistance to ritonavir is not clinically relevant when the drug is used as a pharmacokinetic (PK) enhancer of other antiretroviral (ARV) medications.

Pediatric Use

Approval

Ritonavir has been approved by the Food and Drug Administration for use in the pediatric population.

Efficacy: Effectiveness in Practice

Use of ritonavir as the sole protease inhibitor (PI) in combination antiretroviral therapy in children is not recommended. Although ritonavir has been well studied in children as an ARV agent, it is no longer used as a sole PI for therapy because ritonavir is associated with a higher incidence of gastrointestinal toxicity and has a greater potential for drug-drug interactions than other PIs. Also, ritonavir as a sole PI was associated with a higher risk of virologic failure than efavirenz or ritonavir-boosted lopinavir, and children who developed virologic failure while receiving ritonavir as a sole PI had a high prevalence of major PI and multiclass mutations. In addition, poor palatability of the liquid preparation and large pill burden with the capsules (adult dose is six capsules or tablets twice daily) limit its use as a sole PI. Concentrations are highly variable in children younger than 2 years, and doses of 350 to 450 mg/m² twice daily may not be sufficient for long-term suppression of viral replication in this age group. However, in both children and adults, ritonavir is recommended as a PK enhancer for use with other PIs or, in adults, with the integrase inhibitor elvitegravir when used in combination with another PI. Ritonavir is a CYP3A4 inhibitor and functions as a PK enhancer by slowing the metabolism of elvitegravir and of the PIs.

Dosing

Pediatric dosing regimens including boosted fosamprenavir, tipranavir, darunavir, atazanavir and a PI co-formulation, ritonavir-boosted lopinavir, are available (see individual PIs for more specific information). Dosing of ritonavir when used as a PK enhancer of elvitegravir in a boosted PI regimen is available for adults (see elvitegravir section).

Toxicity

Full-dose ritonavir has been shown to prolong the PR interval in a study of healthy adults who were given ritonavir at 400 mg twice daily. Potentially life-threatening arrhythmias in premature newborn infants treated with ritonavir-boosted lopinavir have been reported; thus, ritonavir-boosted lopinavir should not be used in this group of patients. Co-administration of ritonavir with other drugs that prolong the PR interval (e.g., macrolides, quinolones, methadone) should be undertaken with caution because it is unknown how co-administering any of these drugs with ritonavir will affect the PR interval. In addition, ritonavir should be used with caution in patients who may be at increased risk of developing cardiac conduction abnormalities, such as those with underlying structural heart disease, conduction system abnormalities, ischemic heart disease, or cardiomyopathy.
